No agreement about the proper principle for the distribution of accessibility is in sight yet. But more important than the exact justice principle to be adopted, is the acceptance that the distribution of accessibility *should* be subject to constraints of justice. This is so, because the acceptance of this proposition—that is, that the pattern of accessibility is a concern of justice—has profound implications for the practice of transport planning. It implies that transport planning can no longer be defined as "the field of government intervention that aims to ensure effective and efficient movement". It is this traditional understanding of the purpose of transport planning, with its focus on the functioning of the transport system rather than on the service people receive from the system, that has been responsible for the existing disparities in accessibility, especially between people with and without access to a car, with far-reaching implications for affected people (see [Lucas, 2012](#)). When it is accepted that the distribution of accessibility is a concern of justice, transport planning will have to relate systematically to the existing patterns of accessibility and the impacts of proposed interventions on these patterns. This would lead to a fundamental reformulation of the purpose of transport planning. In general terms, without specifying a principle of justice, the field of transport planning would then be defined as "the field of governance that seeks to *guarantee a fair level of accessibility* for all through the regulation, operation, maintenance, and improvement of the transport system" (see [Martens, 2019](#)). Such a formulation could be easily adapted whatever principle of justice would be agreed upon after due societal debate.

While current transport planning practice is still far removed from this ideal, some countries have made some advancements in this direction. In Flanders, the Law on Mobility Policy, adopted in 2001 and again in 2009, formalizes five objectives among which the goal "to provide everyone with the opportunity to be mobile (. . .) with the aim of full participation of everyone in society", with the latter part of this goal implicitly underscoring the importance of accessibility. While this goal has failed to shape the practice of transport planning, it has resulted in highly detailed guidelines requiring improvements in public transport across the Flanders region. Likewise, the EU-endorsed guidelines for Sustainable Urban Mobility Plans formulated six objectives, the first of which read "ensure all citizens are offered transport options that enable access to key destinations and services" ([European Commission-EC, 2013](#); the objective no longer features in the most recent guidelines). Even more ambitious in aim and scope has been the UK's attempt at accessibility planning ([Department for Transport, 2004](#)). The purpose of accessibility planning was to systematically determine the extent to which population groups at risk of social exclusion could access key destinations for employment, healthcare, education, food shopping, and leisure—and to subsequently propose interventions in the (public) transport system as well as in service delivery to address any gaps. While accessibility planning was disconnected from national-level transport investments and policies and thus failed to address a major cause of disparities in accessibility ([Lucas, 2012](#); [Martens, 2017](#)), it was a bold attempt to seriously address accessibility issues at the local level.

To conclude, the second perspective on transport planning and equity implies profound changes to the practice of transport planning. It would not only require transport planners to analyze the functioning of the transport system in an entirely different way, but also adopt a very different problem definition. It would redirect the focus away from congestion on the network, towards population groups experiencing an unfair level of accessibility. Furthermore, it would demand the adoption of different analytical tools, indicators, and appraisal techniques, ultimately resulting in infrastructure investments, service provision and transport policies quite different from what is currently observed in much of the world.

Transport Planning as a Means to Promote Socio-Economic Equity

In the third perspective on transport planning and equity, concerns over social justice take center stage. This perspective is based on the observation that transport planning as practiced over the past seven decades has been part and parcel of the powerful processes of domination and oppression. These processes have systematically disadvantaged particular groups in society, including low-income households, ethnic minorities, migrants, and women, to the advantage of privileged groups ([Bullard et al., 2004](#)). From this perspective, transport planning is seen as one of the culprits in generating inequalities, poverty and disadvantage in society, rather than as a liberating force enhancing people's freedom of movement. Transport infrastructures, it is argued, are not merely passive artifacts, but shape "(im)mobile subjects" and have produced "unfair privilege" and "disadvantage" as each other's mirror images

(Sheller, 2015). Such a role is deemed unacceptable from a social justice perspective. Transport planning should therefore radically change and become a force of empowerment rather than a tool of oppression (Cook and Butz, 2019), that is, a vehicle to advance justice well beyond the transport domain itself. Hence, I will refer to it as the “radical approach to transport planning”.

It may be clear that merely mapping equity impacts, as suggested in the first perspective presented in this chapter, is not sufficient from the standpoint of this radical approach. Such mapping exercises often fail to shape policy priorities and even if they do so, they tend to maintain the status quo rather than advance radical change. Indeed, the tendency to adopt the principle of proportionality, while intuitively reasonable, does just that: maintain the status quo (Martens and Golub, 2018). This is so, because the principle of proportionality is typically applied to the benefits and burdens generated by an *intervention*, while ignoring existing disparities between population groups. The mapping of equity impacts is thus more likely to be part of the problem than a step towards gradually and systematically eliminating injustices in society.

In a similar vein, the radical approach is also wary about the call to provide a “fair” level of accessibility, as proposed in the second perspective (Verlinghieri and Schwanen, 2020). The argument here is that whenever fairness allows for deviations from equality, such deviations are likely to work to the detriment of disadvantaged groups. From the radical perspective, a principle like sufficient accessibility for all members of society is all but a fair principle, as it is likely to imply that currently disadvantaged groups will have to accept a “sufficient” level of accessibility, while advantaged groups may be expected to enjoy much higher levels of accessibility, either obtained through “free” market transactions or through their influence on inevitably political decision-making processes (Vanoutrive and Cooper, 2019). The same would hold for other types of benefits and burdens generated by transport investments. For instance, if transport planning merely upholds legal norms regarding air pollution, it is virtually inevitable that weaker population groups, in terms of income or ethnicity, are the ones ending up living in the most polluted neighborhoods, certainly in countries with a weakly developed social housing sector.

The radical approach to transport planning also substantially expands the scope of equity. It is not sufficient to address the distribution of goods and bads generated by (the use of) transport infrastructures (Cook and Butz, 2019). Equity in transport planning requires an explicit and open debate about what exactly is at stake—going beyond distribution to concerns over inclusion and representation of “oppressed and disenfranchised groups”, who should be placed “front and center” (Sheller, 2018, p. 28-29). While the other two perspectives tend to be supportive of more inclusionary decision-making processes, they also treat concerns over distribution separately from concerns over representation and recognition. In the radical perspective, no such disconnect is possible.

This call for justice to encompass distribution, recognition and representation is fed by a critical assessment of the presumed progressive role of governments. Rather than assuming that governments act in the common interest and that reason and evidence can convince them to adopt fairness principles in transport, the radical perspective underscores the limited impact of knowledge and argument in the face of entrenched interests. Thus, the approach underscores that “[e]very inch (. . .) will be politically contested” (Sheller, 2018, p. 166), as there are powerful forces seeking to maintain the status quo. Where the two approaches discussed above perhaps implicitly assume that professionals and decision-makers will slowly change practice for the better, gradually embracing concerns over equity and even adopting principles of justice, proponents of this third perspective are far more wary about the willingness to change among key actors. Hence, they call for more radical action. This outlook resonates, for instance, in the work of Karner et al. (Karner et al. 2020) who call for a shift from a state-centered “transport equity” approach towards a society-centered “transport justice” approach, with the latter embracing models of social change that seek to transform state policies from the outside or even create new systems of bottom-up governance detached from those currently sanctioned by the state.

While representation and recognition are key in the radical perspective, questions of distribution remain important. The radical approach insists that, historically, transport planning has contributed to socio-economic disparities in society precisely through the way it has distributed a range of goods and bads. The approach therefore calls for the correction of these historic wrongs, in line with the notion of restorative justice guiding the environmental justice movement in the USA and beyond (Sheller, 2018). The notion of restorative justice requires transport planning to correct past wrongs and thus to become a force of equalization rather than oppression. Such a corrective approach has been adopted in countless environmental restoration processes in the USA (Cole and Foster, 2000), but has seen little following in the domain of transport. Transport planning working in the vain of restorative justice would go beyond merely mapping equity impacts or guaranteeing everyone their “fair share”. Rather, the aim would be to eradicate the existing disparities between population groups, disparities that often are repeated along lines of deprivation such as ethnicity, immigration status, and gender. This applies as much to the vast disparities in accessibility levels, as to the lasting injustices generated by large-scale infrastructures that have ripped apart entire neighborhoods and communities and have burdened them with dangerous pollution levels. Transport planning should correct these wrongs, dedicating substantial budgets to investments and policies that serve disadvantaged groups, so that transport becomes a resource of empowerment rather than a dimension of deprivation.

While radical in nature, some of elements of this perspective have been visible in USA planning practices. An early regulation from the US Department of Transport, dating back to 1970, providing guidelines on how to interpret the Civil Rights Act of 1964 in the domain of transport, explicitly called on transport agencies to take affirmative action to remove the effects of past discrimination (Martens and Golub, 2018). While subsequent guidelines and regulations were less radical in character, the notion of equality and restorative justice is still apparent in transport planning practice in the USA today. For instance, some metropolitan planning organizations explicitly refer to the call for restorative justice in the equity analyses conducted for their regional transport plans. Particularly explicit is the metropolitan planning organization for the Chicago area. In the official “Comprehensive Regional Plan 2040”, in a section discussing the relationship between residential segregation, “equitable access to opportunity” and economic opportunity, it is explicitly stated that “in designing [transport] policies and making investments, it is important to take actions that

do not perpetuate these [employment and income] inequities, and to correct them if possible” (Chicago Metropolitan Agency for Planning [CMAP] 2013b, 48). While such calls are promising steps in the right direction, the impact of equity analyses on decision-making still seems limited at best (see [Lowe, 2014](#)).

Conclusion

The past decade has seen a surge of academic work on transport and equity, as well as an increasing concern in practice over the uneven impacts of transport investments and policies. Much of the academic work is empirical in nature, mapping the uneven geographies in a range of dimensions, from accessibility to air pollution and from traffic safety to transport-related well-being ([Lucas and Martens, 2019](#)), without explicitly addressing the implications for transport planning. In parallel, an increasing number of authors have started to explore the nexus between equity and transport planning, resulting in different perspectives as highlighted in this chapter.

The time seems ripe for change. A range of cities have radically changed their policies, away from a priority for cars, in an effort to enhance urban livability, promote sustainability and create more inclusive transport landscapes. Climate change is forcing a fundamental rethinking of current transport systems and policies, with its heavy reliance on fossil fuels, at all spatial scales. Key institutions, like the EU and The World Bank, have started to address equity issues ([European Commission-EC, 2013](#); [The World Bank, 2005](#)). These developments all suggest that equity will become an even more dominant issue in transport in the future. Whether this will lead to a radical change in transport planning and policy remains to be seen. Transport still stands out from other policy domains, such as housing, education, and health care, with their firm roots in principles of justice. There is still little recognition that the domain of transport deserves or even requires a comparable underpinning. Entrenched perspectives and interests often still dominate. The transport profession is still dominated by an engineering perspective with its ambition to deliver a transport system that ensures “effective and efficient movement”, with little attention for how a supposedly well-functioning transport system serves diverse population groups. Many actors still see transport investments as a way to promote economic development, even if there is little proof of economic impacts of additional investments in regions with an already advanced transport system. And powerful interests related to the car and road building industries obviously have little interest in supporting a radical overhaul of current transport planning practices. The fact that a (car-owning) majority of the population is benefiting from the unjust transport landscapes created over the past decades is certainly also not helpful for achieving change.

We thus conclude that while a “normalization” of the transport domain is urgently called for, such a normalization is not likely to happen without struggle and effort. Academic scholarship can contribute its small share to this struggle by highlighting the inherently political nature of transport planning and by proposing alternative models to the status quo. Hopefully, this article has made its own small contribution in this direction.

Biography

Karel Martens is Associate Professor and Chair of the Graduate Program in Urban and Regional Planning at the Faculty of Architecture and Town Planning, Technion - Israel Institute of Technology (Haifa, Israel), where he also heads the Fair Transport Lab. He holds a master degree in Spatial Planning (1991) and a PhD in Policy Sciences (2000), both from Radboud University, the Netherlands. He has authored numerous publications on the nexus between transport and equity. His book *Transport Justice: Designing Fair Transportation Systems* has been described by colleagues as “groundbreaking”, a “landmark” and “a revolution.”

Introduction

While planning for rail transport shares some common features with planning for other transport modes, rail systems have a number of distinct requirements. This chapter provides a high level overview of the range of issues which need to be considered when planning for rail transport, with a particular focus on those issues which are specific to rail or where the requirements for rail transport differ markedly from those for other modes. Planning for rail transport could involve planning an entirely new rail network, extensions or improvements to an existing network, or changes to services and operations on an existing network, and the scope of this planning will clearly affect the range of factors which must be considered. However, while it would not be necessary when planning minor service changes to review all the factors considered when planning for a new network, the service planning might well still be constrained by the decisions taken when the network was first constructed. It is therefore useful to have an understanding of why these decisions were taken.

It is common when discussing rail transport to differentiate between the requirements of passenger and freight traffic, even though on many rail systems around the world both types of traffic operate side by side on the same tracks. In fact, passenger and freight traffic have many requirements in common, and this chapter attempts to recognize this where possible by considering different traffic types in parallel. However, where these requirements differ the chapter focuses on planning for passenger traffic, due to the limited space available here.

Purpose

The most fundamental questions that have to be answered when planning for rail transport relate to the intended purpose of the infrastructure or service that is being planned. For example, what market is the route intended to serve (or create)? Will the route be used primarily by passenger or freight traffic? Is the route intended to reduce journey times or create additional capacity? Are the new services targeted primarily at short distance commuters or long distance leisure travelers? The answers to these and similar questions will significantly influence the design characteristics of the infrastructure or service that is developed, and a lack of certainty or clarity in this regard can make it extremely difficult to gain support for a scheme. Once the purpose for a scheme has been established, it is then possible to move on to plan the characteristics of that scheme.

Route Planning

It is very rare for complete railway networks to be planned as a coherent whole, and even when such planning does take place (most commonly for urban metro networks) the timescales and costs involved mean that a phased approach to construction is usually adopted. Changing external conditions will often mean that the later phases are then altered or even cancelled. It is perhaps equally rare for rail infrastructure to be planned in an integrated way with investment in other transport infrastructure, especially roads, so that different transport modes complement rather than compete with one another. This is unfortunate, as this lack of integration can

have a negative impact on the business case for transport investments. In particular, if there is a desire to generate mode shift from road to rail (e.g., for environmental reasons), it is best to avoid making parallel investments in both rail and road infrastructure on the same corridor.

It is more common for railway routes to be planned on an individual basis, and these routes will normally be intended to connect two or more key points, and potentially a number of key intermediate points between them. Where railways are built primarily for freight transport these points will usually be a source of raw materials or goods (such as a mine, factory or port), and the market or hub for these goods (such as a factory, distribution center, or outlet for onward transport). In contrast, where railways are built primarily to serve passenger traffic or for a mixture of passenger and freight traffic these key points will usually be settlements, and it is more likely that routes serving these traffic types will also aim to connect intermediate sources of traffic.

In order to maximize potential traffic on the route, the initial aim when planning a route is often to minimize the journey time and/or the transport costs between the start and end points. However, there will almost inevitably be trade-offs between directness and (1) the number of intermediate locations which can be served, and (2) the engineering constraints which have to be overcome and the consequent impact on construction costs. Most rail infrastructure managers in the 21st century set maximum acceptable levels of gradient and curvature (e.g., [RSSB, 2011](#)), which then restrict the potential route options. These are likely to be influenced by the planned operational speed, as in general steeper gradients and sharper curvature will reduce construction costs (as fewer earthworks will be required) but also reduce maximum permitted speeds. The choice of power source for the trains will also influence the maximum acceptable gradient, and may indeed determine whether or not particular routes are viable. For example the Pennsylvania Railroad's extension to Manhattan and Long Island in the early 20th century involved steep gradients on the approaches to tunneled river crossings which were only operationally feasible following the development of electrically-powered locomotives ([Nock, 1979](#), p.34).

As railways are not usually built in undeveloped and uninhabited landscapes, these route options will almost certainly also be constrained by the existing human and natural environment. The topology and geology of the area crossed by a new railway clearly have the potential to affect the feasibility of construction and to increase costs, for example by requiring additional reinforcements to earthworks in order to compensate for unfavorable ground conditions. Increasing concern over the potential for infrastructure to cause environmental damage means that in the 21st century railway planners will also need to minimize the impact of the route on sensitive or protected areas, such as key wildlife habitats and ancient woodlands. There may also be a need to prevent visual "damage" to the landscape.

Railway planning is likely to be particularly constrained in areas where there is already a high density of human activity, that is, in towns and cities. It is usually desirable to minimize the requirement for demolition of existing buildings, as the need to compensate and relocate building owners and occupants will substantially increase scheme costs. The construction of new surface transport corridors through built-up areas also brings the risk of community severance, by inhibiting access between areas on either side of the new route. For these reasons the most cost-effective solution for building railways into urban areas is usually to construct them either overground or (more commonly) underground. The costs of such construction are though still substantial, meaning that the unit costs of railway construction in urban areas will be significantly higher than in rural areas.

As well as the impacts caused by the direct "footprint" of the railway route, there will also be broader impacts on the surrounding environment which need to be considered at the planning stage. For example, train operations may generate substantial levels of noise and vibration, which can have adverse impacts on the local population and also in some circumstances on elements of the built environment. Depending on the power source used for the trains, operations may also contribute to local air pollution, for example near large stations or depots when diesel engines are used ([Thornes et al., 2017](#)). Planners may therefore need to design mitigation measures for these impacts. In practice it is unlikely that a single "optimal" route connecting two points will exist which best accommodates all the constraints discussed above, and several route options will therefore usually be developed for appraisal.

Capacity

Planning an appropriate level of capacity is crucial in order to ensure a railway can accommodate the traffic which it is intended to carry while also keeping costs to a minimum. The capacity of a railway can, in simple terms, be defined as the volume of traffic which that railway is capable of transporting within a given period of time. This overall capacity is then a function of three components: (1) the volume of traffic which can be carried on individual trains; (2) the number of trains which can operate over the railway within a given time period; and (3) the volume of traffic which can be transferred on/off the trains at stations and terminals within that time period. All three of these components will need to be considered when planning for new routes or services, but this section will focus on component 2 as the other components are considered in sections Rolling Stock and Stations and Terminals.

The number of trains that can be operated on a route or network is itself dependent on several other factors. The first of these is the timetable, which sets out the timings and routings for all trains operating on the network, and therefore also implicitly describes the interactions between those services. Timetable planning is both a determinant of and constrained by the capacity of railway networks. When planning for additional services on an existing route, timetabling (and therefore the amount of spare capacity available) will be constrained by the existing infrastructure unless funding is available for enhancements. In contrast, when planning for a new route or network it is advisable to develop the timetable for the route alongside the planning of the infrastructure to ensure that sufficient infrastructure capacity is provided. Two key aspects of the rail infrastructure act to constrain the timetabling of trains, namely the track layout and the signaling design.

The number of trains that can operate on a route will be determined by both the number of tracks provided and the design of “nodes” where tracks interact (Armstrong & Preston, 2017). For example, railways with low traffic levels may only have a single track to accommodate traffic in both directions, with occasional loops provided to allow trains operating in opposite directions to safely pass. In contrast, railways with high traffic levels may have multiple tracks for trains operating in each direction to allow faster and slower trains to be separated. In such circumstances the frequency of crossings allowing trains to switch between the “fast” and “slow” lines will further influence the number of trains which can be accommodated on the route. Similarly, on railways with low traffic levels simple flat junctions are usually provided, where trains operating on to a diverging route cross at the same level the tracks carrying trains in the opposite direction. However, where traffic levels are higher then investment in “grade-separated” junctions may be justified, where the diverging tracks cross other lines via an over- or under-bridge.

Conventionally, most railway routes accommodating anything more than a low density of traffic have been controlled by a “fixed block” signaling system. Such systems divide each track on a route into a series of sections, with only a single train permitted to occupy each section at any given time, and lineside signals used to control access to these sections. The minimum length of these “block sections” is dictated by the minimum distance required to bring a train to a halt using the braking systems available. The length of the block sections will therefore determine the number of trains that can be accommodated on a route, and thus its capacity. Capacity can though be increased by providing “multiple aspect” signals which provide train drivers with advance warning of a danger signal ahead, allowing them to gradually reduce their speed. In recent decades cab signaling systems have been developed which can permit a further increase in line capacity by making use of “moving block” sections. By continuously monitoring the position and speed of all trains on a route, these systems mean that the minimum safe distance to the train in front can be maintained at all times, rather than only at the points where trains pass fixed lineside signals.

The characteristics of the timetable developed for a route will also have an impact on the ability of that route to accommodate additional services. Capacity will be maximized if the services on a route are entirely homogenous (i.e., they all operate at the same speeds and have the same stopping patterns). In contrast, capacity will be reduced if a route is required to accommodate a mix of service types, such as fast intercity services alongside heavy freight services and high capacity local commuter services serving closely-spaced stations. This is because trains operating at different speeds and calling at different sets of intermediate locations will rapidly catch up with one another, and then be delayed until the track layout permits a faster train to overtake a slower one. This problem will be exacerbated if trains have slow acceleration and braking characteristics, which can be a particular issue with heavy freight trains. The capacity issues associated with heterogeneous traffic types can be mitigated to some extent by “flighting” trains in a timetable, where trains with similar speeds and calling patterns are planned to follow one another along a route. However, this may lead to a sub-optimal timetable from the passenger’s point of view, where they are offered several trains to a given destination in quick succession followed by a long gap until the next service.

Rolling Stock

At the time of writing the usual choice of power source for train operations is between electric and diesel power. Electric power (supplied direct to the train via either overhead wires or third/fourth rails) has a number of advantages in terms of operational performance, operating cost and environmental impacts, but also has substantial infrastructure installation costs, which mean that it may be prohibitively expensive for long and/or lightly used routes. “Bi-mode” trains which have both diesel generators and electric current collection equipment are currently in vogue in some contexts (notably the UK), but although they reduce the use of diesel power on electrified sections of route the additional weight associated with diesel engines and fuel tanks means that their energy consumption and performance are inferior to fully electric trains. While some alternative power supply options such as hydrogen fuel cells and batteries are starting to emerge, development has been relatively slow and they are yet to be applied at a fleet-wide scale.

The design characteristics of the rolling stock (trains) required for the route will clearly be dependent on the type(s) of service to be operated. For freight traffic a range of different (and highly specialized) wagon designs are available to carry different types of traffic. For passenger traffic, features like the number of carriages, density and type of seating, and the number and position of doors should be determined based on the characteristic of the route and timetable they will be used for. For example, high frequency urban metro services with frequent stops will usually be operated using relatively long trains with several wide doors per carriage and high density seating with wide gangways to maximize capacity and minimize boarding/alighting times. In contrast, trains for long distance intercity services will tend to have only one or two doors per carriage (usually at the ends), as with fewer stops reducing station dwell times will be less of a priority. However, they will normally be provided with lower density and more comfortable seating (perhaps with tables) and space for luggage storage. They are also more likely to be provided with additional facilities such as toilets, food provision, power sockets, and wifi, although the latter facility is increasingly also an expectation of passengers on metro and suburban operations. Clear information provision is a necessity on any passenger service, and this should be considered carefully when planning rolling stock, taking into account all user groups (e.g., those with hearing impairments will not be able to access verbal announcements about service disruption). Ensuring that trains are accessible to all user groups (including, but not confined to, those with restricted mobility) is also a key consideration, and is now a legal requirement in some contexts. Finally, it is important to remember that rail services are almost always in competition with other modes, and therefore that rolling stock design should aim to provide a positive customer experience (see section Customer Experience).

Stations and Terminals

Planning for railway stations and freight terminals has a number of similarities with planning equivalent facilities for other modes, particularly other public passenger transport modes. Integration with other transport modes is usually of prime importance, because unlike private road transport for virtually all passenger traffic and for much freight traffic rail cannot provide a “door to door” service. Railway stations provide a point of entry to (or exit from) the transport system, an interface between different transport modes, and a facility to store traffic transferring between these different modes (whether passengers or freight). Station planning should therefore be integrated with broader transport planning for the area around the station, in order to ensure that access and egress trips are effectively facilitated.

In general, the aim of station design should be to make the passenger’s transfer through the station as seamless, comfortable and efficient as possible, with similar principles applied to freight terminals. However, the way in which this can best be achieved will clearly vary with the differing characteristics of individual locations and traffic flows. Facilities provided at stations can be divided into those which are required for the operation of the train services (such as tracks and power supplies) and those required to enable passengers to access these services (such as waiting areas, lifts, and information screens). While in theory the only absolutely essential facility at a passenger station is a means of boarding/alighting from a train, in the form of a platform and/or steps on the vehicle, in practice at most stations additional facilities will be provided to enhance either the customer experience or the profitability of the station. The range of facilities provided will usually increase in proportion with the level of traffic at that station, with the smallest stations having little more than a basic shelter and timetable, while the largest stations have a range of retail, catering and entertainment outlets which can make them trip destinations in their own right.

Whatever the size of the station, active and informed planning of the facilities provided will almost certainly deliver a better outcome for the users (and therefore generate more business for the operator). In particular, information provision and wayfinding are key at stations of any size, both with regard to the rail service offered and to facilities for onward travel and key destinations in the surrounding area. At larger stations this may include the provision of dedicated customer-facing staff, while at smaller stations it will rely solely on signage (whether fixed or interactive).

Customer Experience

Planning for both stations and rolling stock links into the more general issue of planning to provide a high level of customer experience for railway users. In recent years, there has been an increased focus on this issue in some countries as railway operators have realized that it can play a key role in attracting discretionary travelers (those who are either making non-essential journeys or who have an alternative transport mode readily available) to travel by rail. Providing a good customer experience is particularly crucial when either the standard of service provided by other modes improves or when rail is unable to gain a competitive advantage over other modes based on price or journey time alone.

Customer experience can be influenced by a wide range of issues, with key factors to consider including information provision, service reliability, response to service disruptions, the quality of the station and on-board environment, and the provision of ancillary services. In general operators should aim to make their passengers (and freight customers) feel like valued customers rather than an encumbrance to the smooth operation of the rail service.

Resilience

Planning for resilience is closely linked to planning for a good customer experience, as a resilient railway will usually also be one which is more attractive to customers. The issue of resilience has become increasingly prominent in planning across a range of infrastructure sectors, with increased awareness of both the vulnerability of infrastructure systems to a range of disruptors and the interdependencies between different infrastructure systems. In order to effectively plan for resilience in railway operations it is necessary to obtain a comprehensive understanding of the vulnerabilities and likely failure points within the railway network, and to identify interdependencies with other systems which could lead to cascading or cross-system failures (Pant et al., 2016). Alongside this, operators will also need to carefully consider the maintenance requirements of their infrastructure and rolling stock, and plan this in a way which minimizes disruption to operations. Together this will then facilitate the production of comprehensive contingency plans for a range of potential disruptions, and the identification of trigger points for the implementation of these plans.

Revenue and Other Benefits

The main direct source of revenue for most passenger railways comes from fares, and it is therefore necessary to plan an effective ticketing system and structure for the route or service. Determining what price to charge passengers and what level of price differentiation to apply is not always straightforward, and can have a significant impact on usage patterns. For example, operators may wish to apply time or service quality-based differentiation to ticket prices, charging passengers more to travel at busy times or obtain a higher level of on-board service. Time-based differentiation can also act as a form of demand management in situations

where travel patterns are highly peaked, reducing the need to provide additional peak capacity. Increasingly rail operators are adopting more sophisticated yield-management systems with the aim of maximizing train occupancy, although by reducing flexibility this can potentially have a negative impact on the customer experience. Operators may also offer discounts to specific groups, whether this is to regular travelers in the form of season tickets, or particular demographic groups (such as students or the elderly) in the form of discount cards. As well as planning a suitable fare structure, operators will need to plan for revenue protection in order to ensure that “fare dodging” is minimized. Tickets are not the only source of revenue available to rail operators, with a number of potential additional revenue streams such as car parking and catering outlets. The potential for revenue generation does though need to be set against the risk that this could reduce customer satisfaction, for example, if charges are levied for facilities which are perceived to be “essential” such as toilets or wifi access.

Alongside direct revenue generation, railways can often deliver a range of other societal and economic benefits (Whitelegg, 1987), such as reductions in congestion and pollution and increased levels of accessibility to employment and key services. This means there can often be a strong argument for subsidizing rail operations which do not meet their direct financial costs, but it is important that any claimed benefits for a particular rail route or service are backed up by robust evidence and methodologies in order that the limited money available for subsidizing transport services is allocated to the most appropriate recipients.

Conclusions

The previous sections have provided an overview of the range of factors which need to be considered when planning a railway route or service. It is clear from this discussion that such planning is potentially highly complex, and in order for it to be undertaken effectively planners must consider the interdependencies between railways and other transport, infrastructure and land use systems. Nonetheless, if planned well railways have the potential to play a very significant role in addressing the transport challenges facing 21st century societies. They remain unrivalled in their capability to efficiently transport large numbers of people to and from urban centers and along interurban corridors, and are perhaps easier to decarbonize than any other mechanized transport mode. It therefore seems clear that planning for rail transport will continue to be an important task for the foreseeable future.

Biography

Simon Blainey is an Associate Professor in Transportation at the University of Southampton, with 13 years of experience in transport-related research. He has particular expertise in railway demand and operational modeling, and in strategic transport modeling and planning. He is programme lead for the University of Southampton’s MSc in Transportation Planning and Engineering, and leads the module on “Railway Engineering and Operations.”

Introduction

Connected and Autonomous Vehicles (CAVs) will revolutionize automobility as we know it by passing on the vehicle control and driving responsibilities from the hands of human beings to autopilots with immense Artificial Intelligence (AI), Machine Learning (ML) and wireless connectivity capabilities. More specifically, on the one hand CAVs will be connected, meaning that they will be able to communicate information wirelessly with other vehicles (vehicle-to-vehicle or V2V communications) and with other sources including built environment infrastructure (vehicle-to-infrastructure or V2I communications), control centers supervising the transport system operations and external sources such as weather forecasting operatives (vehicle-to-everything or V2X communications). On the other hand, CAVs will be autonomous, meaning that they will perform driving tasks without human input. CAVs will scan their surroundings through a combination of sensors, cameras, radars and a Light Imaging Detection and Ranging (LIDAR) system and through AI and advanced control systems they will interpret the collected sensory information to detect obstacles and choose the most fitting navigation path.

CAVs are also expected to be the key apparatus for shifting to a transformative automobility narrative crafted by synergies between automation, connectivity, which define the identity of CAVs anyway, but also between electrification and shared use, which are of critical importance if future mobility is to promote sustainability. The synergistic effects between vehicle automation, connectivity, sharing and electrification can multiply significantly the benefits of CAVs as also noted by [Milakis et al. \(2017\)](#). CAVs are projected therefore, to be the immediate successor of the human-driven, conventionally fuelled, privately owned, unconnected vehicle that was the epicenter of urban development and defined the ways cities have been designed and built for many decades ([Nikitas et al., 2019](#); [Thomopoulos and Nikitas, 2019](#)).

Henceforward, the paper introduces, in the next section some of the key opportunities and challenges that may be directly associated with a full-scale launch of CAVs; these are listed as CAVs projected benefits and side effects. The paper also introduces 10 critical areas that policy-makers, planners, and future mobility providers need to look carefully when developing policy instruments, designing planning initiatives, and putting together strategic visions. Finally, a conclusion section describes the pathway to the driverless transition and the role of CAVs in a diverse future urban mobility era.

Projections About CAVs Benefits and Side Effects and Why it is Important to Plan

CAVs have gained traction across the globe with automotive industries, technology providers, ride-hailing companies, and policy stakeholders setting out plans and making multi-billion investments to enter dynamically and from a pole position, the arena of automated, connected and digitized transport. This is because CAVs are projected to be at the epicenter of a new and unprecedented travel eco-system with transformative powers for cities, societies, and economies ([Nikitas et al., 2020](#)).

CAVs may offer, at least in theory, an overwhelming potential for positive change in terms of reducing traffic accident, injury and death rates, road traffic congestion levels and travel delays, CO₂ and greenhouse gas emissions, noise nuisance, energy consumption, mobility-related social exclusion for those currently unable to drive, inefficient routing, parking requirements and enabling improved in-vehicle productivity and relaxed driving experience ([Fagnant and Kockelman, 2015](#); [Nikitas et al., 2017](#); [Thomopoulos and Givoni, 2015](#)).

Nonetheless, at the same time CAVs are considered a disruptive technology that will impose an entirely different mobility paradigm with many diverse challenges, some of which cannot be even predicted for now. If not implemented in a systematic, well-calculated, and cautious way, CAVs could create new barriers relating to vulnerability to hacking, software and hardware flaws, loss of privacy and personal space, increased traffic through greater car dependence or just running empty vehicles, behavioral adaption and user resistance problems, integration problems with other components of the new travel eco-system and loss of many current driving-related jobs ([Nikitas et al., 2020](#)).

The stakeholders responsible for the transition to CAVs should be aware of this wide range of opportunities and challenges, each of which may (or may not) be associated with an eventual large-scale launch of this technology. Effective planning and a pro-active approach are therefore necessary and will enable a smoother and more resource-efficient shift.

The Key Themes for CAVs Policy: Understanding Where We Are and Avoiding the Bumps Ahead

There are many issues that remain uncertain about how this CAV-oriented revolution will unfold. At the same time there are some givens that could inform the direction of the strategic vision and planning behind CAVs implementation; areas that can be highlighted as vital ones and need more research and development contributions. Academia, industry, business, and governing authorities in every level need to intensify their efforts in creating strategies that address these thematic areas.

These critical areas of priority, categorized according to what is known today, refer among others to: *technology maturity; legislation and responsibility; crisis and employment ethics; infrastructure, built environment and land use; integration with the non-connected modes; traffic safety and accident prevention; cyber security and privacy of personal space and data; business models; traffic congestion and travel behavior; and finally acceptability, trust and customer readiness.*

Technology: CAV-related technology has developed a lot. Millions of miles have been already performed by AVs in segregated, in most cases, environments where interaction with other vehicles is closely monitored and significantly controlled. But these early driverless cars are still basic prototypes of what is forecasted to be a fully operational CAV; they can only detect and avoid objects on typical (and usually pre-selected) transport scenarios but are not yet able to anticipate and fully respond to complex traffic behavior that is atypical or unprecedented and usually comes from non-motorized travelers. Teaching the car how to respond to what can be described as ‘the long tail of unlikely events’ such as a plastic bag blowing across the motorway, a couch sitting in the middle of the road (Waldrop, 2015) or unorthodox pedestrian or cyclist behavior is vital, and is an achievement that is yet to be attained in terms of technology (Nikitas et al., 2019). Also, the AV prototypes close to production today, are still seriously lagging in terms of their ability to communicate in real-time and thus connect with other vehicles and the road infrastructure. Technology needs to shape CAVs per se but also re-shape the whole travel eco-system that will host them.

Legislation: Despite being the cornerstone of every socio-technical innovation establishment, legislation has not yet reached the same level of maturity as technology and thus it is still a key barrier to CAVs implementation. In order for CAVs to deliver on their promise without becoming a disruptive technology that for a short-term, at least, could jeopardise the urban landscape equilibrium there is a need for them to operate based on a legal framework that is completely different from the one dealing with the conventional human-driven vehicle of today. Road traffic regulations, liability allocation, responsibility patterns, enforcement strategies, data privacy laws, road standards and safety assurance regimes are not yet fully (or at all) developed and there are no consistent universal standards. Policy-makers need to work systematically in establishing laws and regulations that will support the legal and safe implementation of CAVs.

Crisis and employment ethics: At the same time CAVs are underpinned by a moral dimension, unprecedented in the design of socio-technical innovation, creating questions that unless convincingly addressed they can bring any progress to a stalemate. What should be the computer’s decision-making criteria for choosing from a set of crash trajectory alternatives? What is more important in an unavoidable crash scenario, the self-interest or the public good? CAVs might need to choose between for instance running over pedestrians or sacrificing their passengers to save the pedestrians (Bonnefon et al., 2016) and there is not yet a clear consensus of what is the “right” and “ethical” option. Establishing what constitutes ethical behavior in emergency situations is a hard philosophical problem (de Sio, 2017) that policy-makers primarily, and mobility providers secondarily, need to solve. A second ethical issue of transformative proportions that decision-makers need to address refers to CAVs’ potential to create an unprecedented labour market disruption. How should we respond to the possible loss of millions of driving-related jobs? How can we replace all these jobs on the short- and long-term and how could we re-skill the people affected to be re-employable? Should we even proceed with a full-scale launch of CAVs if we cannot guarantee that the job market will rebound? Those responsible for the transition need to implement CAVs without creating a new colossal layer of employment-related social exclusion.

Infrastructure and land use: Refiguring out and rebranding infrastructure while planning built environments so that they include CAVs must be prioritized by researchers, policy-makers and smart mobility investors. There is a need for building a more tailored road environment that caters for CAVs’ special requirements in terms of connectivity, communication, coordination and digitalization. This smarter road transport environment will need to include sensors, data capture capabilities, state-of-the-art CCTV and traffic signal systems, the ability to be responsive to changes in the environment, electrical charging provision, adaptable street lighting and more importantly the ability to “talk” to different vehicles and road users (Nikitas et al., 2019). Land use policies and plans should support and be supported by CAV services. Transit Oriented Development (TOD) employing CAVs as first and last-mile solutions and neighborhood feeders to more mainstream mass transit systems may be an uneasy union because of their traditionally contradictory roles but future planning efforts need to blend them successfully and propose them as a balanced solution to land use development (Knowles et al., 2020).

Integration: Creating CAVs with the capacity to detect and understand the movement of other forms of non-connected and non-motorized transport modes and respect their travel needs is essential not only for safety and accident prevention but also in terms of achieving efficiencies and traffic optimization. The travel eco-system of the future should not operate under the presence of a CAV-induced dichotomy with some parts of the system understanding and co-functioning with CAVs and some not; there will be the need for a unified, homogeneous and integrated future mobility system. Human and machines speak different languages for now and this

has to change. Human-machine interactions need to be unproblematic, smooth, and effective. Until technology and policy-making bridge this gap between driverless cars and, for example, active travelers, CAVs will not be ready to be safely integrated in the mobility paradigm and maximize their potential in efficiency optimization.

Traffic safety: As long as human drivers are safer than driverless vehicles, it will be unethical to sell them (Sparrow and Howard, 2017). CAVs will need to surpass the human decision-making process when it comes to accident prevention and there is a pathway to do so since human error, the principle factor generating traffic accidents today (Thomas et al., 2013), can be eliminated or minimized with machines driving. By doing so, CAVs will not only help create significantly less traffic crashes, injuries, and deaths but erase some of the key side-effects of accidents, including production losses and massive costs on our healthcare systems. However, if the transport system is a mixed traffic system including large numbers of semi-autonomous and non-autonomous vehicles, low levels of vehicle connectivity and interaction with non-motorized travelers, the possible benefits of CAVs may be in jeopardy. It is still unclear whether CAVs may actually be more prone to accidents in a scenario where there is so much heterogeneity in the system, and where there is limited integration, synchronization, and interoperability.

Cyber security and privacy: One significant factor that may control to a disproportionate degree the acceptability, approval, and uptake narratives is how CAVs could effectively respond to their vulnerability to cyber threats and data sharing exploitation that may have negative effects in both security and privacy. The increased level of the computational functionality and connectivity that CAVs will be able to provide will increase their exposure to prospective vulnerabilities (Parkinson et al., 2017) and opportunities for data mismanagement. CAVs capacity to store and transmit travel, transaction and lifestyle data, make them potentially attractive targets for hackers. Such information can be easily sold for financial gains, or these systems could be used to inflict physical harm by extremists or used for illegal purposes by drug traffickers (Taeihagh and Lim, 2019). Unauthorized hacking and cyber-terrorism on the one hand, and private data sharing and loss of personal space (especially if CAVs end up being shared) on the other, are all policy and planning challenges that need to be addressed effectively for the travelers of the future.

Business models: The transport industry cannot move to the future under the conventional monolithic industrial structures, business models, and operational practices that have defined over 100 years of automotive history. The traditional auto-manufacturers will need to recraft their business approaches, having to compete and form synergies with a new breed of high-tech competitors including mega-players such as Google, Tesla, and Uber. Business models and their respective policy paths need to be flexible and resilient to uncertainties as recommended by Lyons (2016), while their viability should be assessed in cost structure competitiveness terms (Bösch et al., 2018). One of the paradigm-shifting concepts that will revolutionize the current modus operandi is the shared automated vehicle (SAV) which will convert the notion of travel from one that is largely carried out by privately held personal vehicles to fleet services by driverless, demand-responsive vehicles, shared (or for hire) across a mix of users (Fagnant and Kockelman, 2018). Litman (2017) argues that private vehicles might be completely displaced by SAVs that according to Narayanan et al. (2020) can be classified into car-sharing, ride-sharing, and mixed systems. SAVs are projected to be the key to the new holistic transport provision regime known as Mobility-as-a-Service (MaaS) that will replace privately owned transport with personalized mobility packages that give access to multiple travel modes, smart ticketing, and real-time information on a need-only basis via powerful digital platforms. A private ownership-based automation paradigm may be problematic because of the high cost of the vehicles and the need for a higher level of coordination that isolated ownership cannot offer (Nikitas et al., 2019). Private vehicle ownership might still find ways to survive but for the first time there will be a serious possibility that it will be severely overshadowed by car-sharing and ride-sharing services.

Traffic congestion and travel behavior: CAVs, in an ideal scenario, could produce traffic congestion savings due to their adaptive cruise control measures and traffic monitoring systems by minimizing accelerations and braking in freeway traffic and by optimizing road space use (Fagnant and Kockelman, 2015). This could increase fuel economy and congested traffic speeds significantly depending on V2V communication and how traffic-smoothing algorithms are implemented (Atiyeh, 2012). At the same time though, unoccupied vehicle miles traveled could become a real concern that would add an extra layer of road traffic congestion that does not exist today. Although, vehicle ownership may be reduced or even vanished, by providing an unprecedented ease of access, CAVs are projected to enable more people to travel more regularly and for longer distances and could even tempt individuals currently using public transport services to replace some of these trips with SAV services. Unoccupied vehicle trips and unsustainable travel behavior habits may create a congestion-generating puzzle that can only be solved if CAVs are implemented following strict sustainability rules. Investment in automated public transport, travel demand management and traffic calming measures could become even more necessary in the era of CAVs, to balance out these possible planning and policy side-effects.

Customer readiness, acceptability, and trust: Policy-makers and planners need to pro-actively recognize that customers may not be ready yet, despite the entire media buzz, for the monumental cultural transition that a driverless revolution implies. While in hypothetical scenarios, a priori acceptability of CAVs could be likely for many drivers today (Payre et al., 2014) the universal acceptance of CAVs, when these arrive to replace conventional cars, is not definite (Nikitas and Nikitas, 2015; Nikitas et al., 2017). The public may need to overcome socio-psychological barriers that stand in the way of widespread adoption (Shariff et al., 2017) including according to Schoettle and Sivak (2014) and Kyriakidis et al. (2015) concerns about security and cyber security threats, driving performance, unoccupied vehicles increasing road traffic, lacking the joy of driving and regulation absence. Users might need to be persuaded that a shift is safe, sustainable and beneficial to them. Trust is also a process that needs time and transport innovations generally require a period of familiarization (Nikitas et al., 2018). With acceptability being the “maker or breaker” of a smooth shift to CAVs, the key stakeholders need to, on the one hand, invest in marketing campaigns that make customers aware of the benefits of autonomous driving with an emphasis on word-of-mouth and consumer-to-consumer marketing, and on the other hand develop education, training, consultation, and engagement exercises that help people acknowledge what CAVs have to offer.

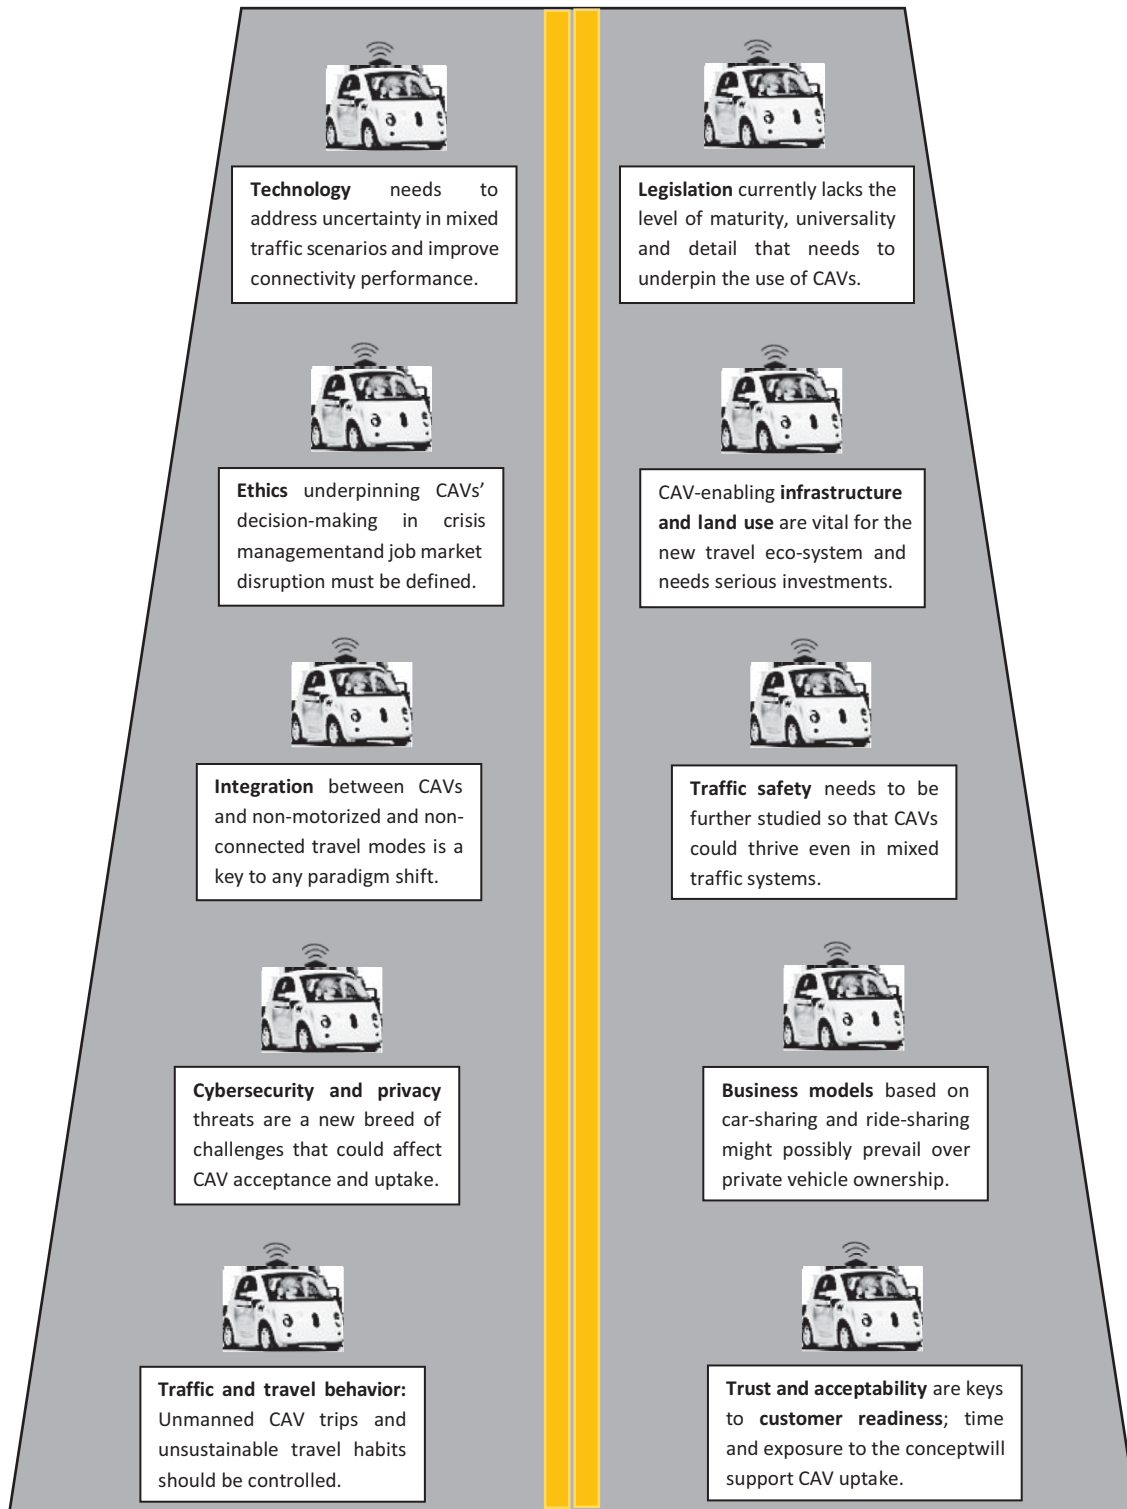

Figure 1 Priority areas for the planning and policy of connected and autonomous vehicles.

Fig. 1 presents an illustration summarizing the key priority areas for the development of CAVs when considering the needs for transport policy and planning. It ultimately provides a concise roadmap about the magnitude and diversity of the steps and challenges underpinning a shift to a CAV-centric mobility paradigm.

Conclusions and Key Policy and Industry Recommendations

Transitioning to CAVs is a lengthy and complicated procedure that requires from policy-makers, planners and mobility providers a strategic approach based on patience, perseverance, and flexibility. Investments on the technology of CAVs alone are not enough; technology on its own, much like Sochor and Nikitas (2016) described it, can only be “one of the several tools in the toolbox of mobility.” Legislation, infrastructure, education, research, and development investments are also critical and should be consistent, balanced, and significant. Implementing CAVs cannot and should not be rushed. This transition will not be about getting there first, but about getting there safely and securely. A full-scale launch must occur only when planning efforts reach a level of maturity that will answer most of today’s unanswered questions. CAVs should incrementally grow on a tactical and systematic basis. They should start from small-scale controlled schemes studied in living labs to allow research and development stakeholders to understand them better, and only then expand in a controlled and calculated way. Piloting and trailing exercises designed to raise awareness and promote engagement with customers and the general public, are critical for any such transition. Some trials may go wrong before the right formula for successfully operating CAVs is found; thus the key stakeholders of future mobility should be ready to respond to failures, accidents, and the backlash that these might generate. It should be clear that CAVs are not a panacea that will fix all that is wrong with transport today; CAVs cannot and will not solve all the traffic problems on their own but they can be a significant component to a more holistic solution (Nikitas et al., 2019). To maximize their potential for positive change and help “building” the smart cities of tomorrow, CAVs might need to potentially work under the principles of MaaS and be complemented by other powerful mobility initiatives like TOD, automated public transport, travel demand management tools, and traffic calming measures.

Biography

Dr. Alexandros Nikitas is a Senior Lecturer in Transport for Huddersfield Business School at the University of Huddersfield, United Kingdom. He is the Deputy Director of the School’s Behavioral Research Center and a co-investigator of the University’s European Structural and Investment Funds project LCR LEP Supply Chain. He is a member of the Editorial Boards of the Journals *Research in Transportation Business & Management* and *Case Studies on Transport Policy* and has produced more than 70 papers and conference outputs in his career thus far. He is conducting research regarding the societal importance of autonomous, connected, shared and sustainable transport. Earlier in his career Dr. Nikitas was a Senior Researcher in Urban Futures and Transportation for Chalmers University of Technology, Sweden where he worked on FP7 and H2020 initiatives. He has been an invited visiting scholar for Tongji University and Chang’an University in China and EC’s Joint Research Centre, Ispra, Italy. He was also a Local Councilor for his hometown Drama, Greece between 2011 and 2014.

Introduction

In 1994, Rosenbloom and Burns published their article *Why working women drive alone: Implications of Travel Reduction Programs*. The authors asserted that since the 1970s, there was a significant increase in the role of the car coupled with the declining use of transit and car-pooling. The growing concerns of pollution, and traffic congestion led to the passing of The Intermodal Surface Transportation Efficiency Act (ISTEA) and the Clean Air Act Amendments of 1990. Both acts mandated that employers and governmental agencies must incorporate Travel Demand Management (TDM) programs aim at reducing car trips to work, so they focus on raising fees for parking cars, changes in work schedules, and alternative modes to get to work. Through their study, Rosenbloom and Burns (1994) showed that TDM programs did not alter travel patterns because cars are a necessity and not a luxury for most working women with families. The researchers who had advocated travel reduction programs did not fully understand that punitive measures to reduce vehicle trips would disrupt the work-life balance of working women. In this article, I take the conversation and deep dive into gendered work and how that shapes what I call "gendered mobility".

Different Facets of Women's Work

If we truly want to improve mobility for the women, we must understand and recognize visible and invisible work that they routinely complete. Throughout the day, women make intricate decisions and accompanied trips based on their role as employees and moms. In *The Time Bind*, Hochschild (1997) conducted series of interviews of couples and one of them was Mario and Deb Alcala. Mario was a regular shift worker with 20 additional overtime hours. Deb had 5 h of overtime along with rotating 7-day shift. The couple had three children. Hochschild describes Deb's schedule as a railroad switchman constantly switching her schedule and travel patterns to meet the demands of childcare and work (Hochschild, 1997).

Hochschild's (1997) narrative plays out in every household in the U.S. and in other countries. Women usually are in charge of managing their family schedules. In most cases, the unpaid work hours and the accompanied trips are not fully reported at regional and local levels. OECD (2017) has been collecting data on paid and unpaid work minutes per day by gender for selected countries since 1960s. In 2014, women between the ages 15–64 years worked less hours but had much higher unpaid hours than the men (15–64 years) and for some countries, Greece, Japan, Korea, Turkey, and Portugal there is marked difference in unpaid work each day (OECD, 2017). The effect of gendered work affects the time of the trips, complexity of the trips, trip mode heavily influenced by the socio-economic status of the women. If we want to focus on improving mobility for the women, we have to acknowledge the multiple roles taken by women both as workers and caregivers.

Gendered Work

In the 1960s and early 1990s, progressive middle-class white women entered the labor market (Becker, 2010; Tossi, 2002). By 2000, 74.8% of men and 60% of women in the United States were in the workforce (Blau and Kahn, 2007). It did not take long, for family scholars to observe that women's trips had two demanding sets of responsibilities, one was home-related and the other was work-related (Ridgeway and Correll, 2004). Although the role of women in society changed, they were still expected to take full responsibilities of the socio-emotional needs of the family members (Levinger, 1964; Rothschild, 1983). At the same time, feminist scholars observed that the rise in women's income did not increase men's domestic work. They argued that household labor continued to be mostly assigned to woman. This categorization of household work as "wifely" and "husbandly" roles reproduced dominant and subordinate status based on gender (Berk, 1985; West and Zimmermann, 1987).

Until the 1980s, women's household work trips were not recognized and remained invisible because it was unpaid. Arlene Daniel's (1987) gave "dignity" to women's work (inside and outside home) by reminding researchers that women's unpaid work and trips are complex and should not remain invisible. Other family scholars too have insisted that women's contribution in family, social, and community life that was unpaid must be included along with their paid work (Shelton and John, 1996). Around the same time, sociologists started talking about the emotional support (emotional sustenance, socioemotional role, therapeutic role) provided by women at home, work, and as volunteers (Berk, 1985; Hochschild, 1989; West and Zimmerman, 1987). Emotional support work makes others feel cared for and loved and enhances others' well-being (Erickson, 1996). These activities require time, effort, and skill and is known as "emotion work" (Hochschild, 1979). Erickson (2005) explained that showing appreciation, being a good listener, empathizing with another person's feelings (without reciprocation) for the long haul represents emotion work of the highest order (Erickson, 2005). There is no data collected on the number of minutes of "emotion work" by gender.

Women have self-imposed restrictions on the distances they are willing to travel for work or the number of hours they can work because they shoulder bulk of the routine housework childcare, and chauffeuring services (Ren and Kwan, 2009). Unfortunately, the self-imposed job constraints and/or reduced working hours per week affect their take home pay and career prospects (Golden, 2015).

Women's role in "concerted cultivation" of children is considered unpaid emotional labor (Lois, 2010). In her 2003 book, *Unequal Childhoods*, Lareau explained "concerted cultivation" style is used by the middle-class families to raise their children. The middle-class kids are driven to soccer practice and band recitals, and many other extra-curricular activities throughout the year (McKenna, February 16, 2012). This form of emotional labor requires many unpaid trips. Other literature dealt with the barriers to mobility for those specially-abled mothers and the consideration for "intensive mothering where paid care-takers or nannies take on the hours and trips associated with children (Christopher, 2012; Frederick, 2018). There is indeed a gap in the literature that quantifies the value of unpaid labor and the number of trips in transportation research.

Gendered Work and Mobility: Complex Social Constructs

Right around the time when sociologists, family scholars were writing about the invisible work by women (Berk, 1985; Hochschild, 1979; West and Zimmerman, 1987), feminist geographers were insisting that daily travel patterns from home to work should not be gender blind (Radcliffe, 2006). Transportation scholars started noticing that the women had shorter work trip lengths on average but with complex nonwork components (Hanson and Pratt, 1995; Wachs, 1998). Gordon et al. (1989) analyzed the Nationwide Personal Transportation Study (NPTS) surveys of 1977 and 1983-83 and found these large increases in nonwork trips were taking place mostly during peak hours and that women encountered higher levels of day-time fixed nonwork trip constraints than men. Using 1990 NPTS data, Strathman et al. (1994) found that women completed errands on their way to and from work 42% of the time, while men completed errands 30.6% of the time. The trip chains were higher for women in all categories (simple work, complex work, simple nonwork, and complex nonwork) and they varied with family and life-cycle status (Srinivasan, 2000; Strathman et al., 1994).

In households with children, women create complex trip chains substantially more than women in households without children, or than men. Many of the trip chains are to fulfill the growing need of concerted cultivation, but travel behavior models have not generated models looking into the increased trips due to concerted cultivation. Single mothers, especially of small children, are far more likely to create trip chains than either single fathers or mothers in households with two adults (McGuckin and Murakami, 1999). Nonwork travel is among the more challenging travel activities to study. Most importantly because they vary by socio-economic characteristics and gender. It is nonsystematic, and in many cases, fixed. They constitute the majority of travel activities, including shopping, personal business, and accessing healthcare, schooling, and others (Horner and O'Kelly, 2007).

Women "Opting-Out" of Careers or "Pushed-out" due to Policies

Among married-couple families with children, 63.0% (22.3 million) households had both parents employed (U.S. Bureau of Labor Statistics, 2020). However, for 37% of the families, the father worked and the mother worked part time or did not work. In these households, the women took up most of the household and childcare work.

Workplaces are far from family-friendly (Moore, 2018). In her study of 54 "opt-out" mothers, Stone (2007) found that addition to work, the unavailability, inability, and/or unwillingness of husbands' to take up family responsibilities also played an important

role in quitting. VerBrueggen and Wang (2019) showed that in the US 46% of the mothers whose husbands earned \$250,000 or higher a year were not in the labor force. Also that 35% of mothers whose husbands made less than \$25,000 a year were stay-at-home moms because of unaffordable childcare. While those married to husbands with an income between \$50,000 and \$75,000 are the least likely to stay at home; only 25% of them were out of the labor force.

Gender Pay Gaps, Family Penalty, and Commuting Costs

Traditional gender roles and women's greater responsibility for unpaid work has continued to negatively affect women's labor market outcomes. Blau and Kahn (2017) used Panel Study of Income Dynamics (PSID) microdata over the 1980–2010 period to assess the wage gap by gender. They reported that the female/male earnings ratio was around 60%. Blau and Kahn (2017) found that women's relative wages began to rise sharply in the 1980s, but became slower in the later years. By 2014, women full-time workers earned about 79% of what men did on an annual basis and about 83% on a weekly basis (Blau and Kahn, 2017). Economists mention that certain gender-specific factors explain the lower earnings of women. Some of these factors that cause wage differentials such as shorter hours, when children are young, changes the balance between wages and commuting costs as the commuting cost is not fully recovered.

Flexible Schedules and Telecommuting

While women have forged ahead in labor participation, the gendered role has caused distinct pressure to seek professions that enable them to fulfill the work associated with homes (Chung and van der Horst, 2017). Women select jobs that allow them to have a flexible schedule to support nonwork trips (Williams and Bornstein, 2006). The concept of flexibility or schedule control focuses on control over *when* work is done instead of *how* it is done (Kelly and Moen, 2007). This concept if used well, could assist women to keep their jobs and not worry about how to create work-life balance and reduce the need to travel.

Telecommuting workers are more likely to be managerial and professional workers with higher salaries and higher educational attainment. Schedule control in Germany showed that men benefited more from flex-control through overtime and income because when mothers work from home, they are more likely than fathers to do so during standard work hours (Glass and Noonan, 2016).

The Federal Highway Administration (FHWA) has been collecting data on the number of people working from home. Based on this data for the US, it seems that the telecommuting jobs are geared more towards the managers, and those who are low-income (Table 1).

Telecommuting for Climate Action and Family Friendly Policies

In the US, The Clean Air Act amendments of 1990 established telecommuting programs in cities with severe air quality conditions to investigate whether a reduction in emissions could be achieved. The 2010 Telework Enhancement Act renewed provisions for telecommuting policies in US federal agencies (Lari, 2012). While telecommuting is still often presented as a sustainable travel policy, its use remains limited and its effects on reducing overall travel time and peak period travel unclear. The researchers and employers need to shift the focus of telecommuting from an environment-friendly policy to a family friendly, gender friendly policy (Glass and Noonan, 2016).

Transportation Policies that support Women in Poverty

In 2016, women made up nearly 67% of the 24 million workers in low-wage jobs in the US (defined as jobs that typically pay \$11.50 per hour or less), though they make up slightly less than half (47%) of the workforce. Low-wage workers are a racially diverse group, and disproportionately females. Ross and Bateman (2019) reported that 52% are white, 25% are Latino or Hispanic, 15% are Black,

Table 1 Longitudinal trend in home-based Working by Income, Occupation and Home Location

Poverty level	1995	2001	2009	2017
Household Income				
<\$50,000	59	28	17	30

and 5% are Asian American. Those below the poverty level are disproportionately Blacks (21.7%) and Hispanics (18.3%), and proportionately more women are below the poverty level ([Ross and Bateman, 2019](#)). These women are in no position to influence policy changes or advocate for improved transportation system ([Ferragina, 2013](#); [McLanahan et al., 1994](#); [Townsend, 1987](#)).

Role of Transit for Female-headed Minority Households

A disproportionate number of female-headed households used transit because it provides mobility for those who are carless ([Blumenberg and Pierce, 2012](#); [Rosenbloom, 2006](#)). African-American women and Latina with low average wages rely more on public transit when compared to white women in the US ([McLafferty and Preston, 1991](#); [Metro, 2019](#)).

Although the overall number of transit trips have dropped in 2017 for all income groups, the households with lower income made the most transit trips ([Fig. 1](#)). Immigrants in general, commute by public transit at twice the rate of native-born commuters in metro areas ([Fig. 2](#)). However, since access to jobs is closely related to how reliable and efficient the public transport systems are, immigrants may start off by being transit-dependent but as years pass, they progressively opt for cars over transit as seen in [Fig. 3](#) ([Blumenberg and Evans, 2010](#)).

Needs of Women in Public Transit

Women with better access to transit have lower rates of unemployment. Efficient public transportation systems enable women to access jobs and economic opportunities ([Blumenberg and Pierce, 2012](#)). And yet, transit agencies fail to recognize that due to gendered division of labor, women have different travel patterns than men. In an initiative led by Metro's Women and Girls Governing Council, Los Angeles County Metropolitan Transportation Authority (LA Metro), became the first transit agency in the U. S. that acknowledged that there was a gender data gap and published, *Understanding How Women Travel (UHWI)*. After collecting qualitative and quantitative gender data through a survey that was completed by 2600 residents; qualitative data was collected through pop-up engagements at key rail stations; and focus groups with women riders who were diverse, such as, immigrants, have disabilities, or are experiencing homelessness ([Metro, 2019](#)).

Women's Fear of Victimization

Transit users spend a considerable amount time in public places, bus stops, transit stations, transit vehicles. Women's safety is most compromised in such place and in public transport. Mass transit moves large amounts of people through a city and shapes the crime pattern along a limited number of paths. The women who responded to Metro's survey identified safety concerns as the top barrier to use transit. Over 80% of women transit users felt unsafe walking to transit stations, waiting for transit and riding transit in the

Figure 2 Transit usage (Percent) by place of birth among immigrant workers. Source: Own Working from Chatman, D.G. and Klein, N. (2009). *Immigrants and Travel Demand in the United States. Public Works Management & Policy*, 13(4), pp.312–327. Data from: Table 6.

evening Men felt unsafe too, but the responses were lower, although waiting at the transit stops was found to be least unsafe (70%) (Metro, 2019).

It is difficult to objectify women's fear when they are in public places at night. Desolation, darkness and lack of activity or natural surveillance in a transportation setting contribute to anxiety and the fear that no one will be there to help if a crime occurs (Loukaitou-Sideris, 2006). Fear of victimization in public settings is influenced by age, race, class, cultural and educational

Table 2 Responses (Percent) of Women by age and transit usage (300-700 respondents who responded to these question)

Source: Own Working from: D'Arbois de Jubainville, H. and Vanier, C. (2017). Women's avoidance behaviors in public transport in the Ile-de-France region. *Crime Prevention and Community Safety*, 19(3-4), pp.183-198. Data from Table 3.

background, sexual orientation, prior victimization experiences, and disability status (Gardner et al., 2017). Fear modifies choices women make as pedestrians and passengers (time of journey, where they wait for a train, where on a train they sit). Whether being rooted in real or only perceived danger, fear has significant effect on women's travel patterns. Women adopt a range of behavioral mechanisms when in public to choosing specific routes, modes, and transit environments over others to completely avoiding particular transit environments, bus stops and/or walking and biking (Condon et al., 2007; Loukaitou-Sideris, 2006). How does this fear relate to social exclusion and trip avoidance?

The micro-spaces of transportation nodes influence the perception of safety in systems. Micro-spaces refer to façade, the density and height of the buildings, the number and types of streets and entrances, transit stops but also urban design features, such as seating, storefronts and other physical environments (Ceccato and Moreira, 2020; Loukaitou-Sideris, 2006). The very nature of transit stops facilitate robberies. Transit stops are public spaces which allow easy entry and exit, and standing around is not deemed suspicious and the potential targets are most likely walking (Block and Block, 2000). Some researchers contend that subway stations are also crime generators (Block and Block, 2000; Piza and Kennedy, 2003). While analyzing the French national victimization survey (2010-13), D'Arbois de Jubainville and Vanier, 2017 found that young women feared traveling late in the evening felt most unsafe in station surroundings, presence of rude passengers, and when there are fewer people in the stations (Table 2). Surveys on security conducted in the United State, United Kingdom, and in India since the mid-1980s found that waiting at the bus stop was a major source of concern and fear among women (Levine et al., 1986; Loukaitou-Sideris, 1999; Mitra-Sarkar and Partheeban, 2011).

Private Vehicle Ownership and Poverty

Public transit systems in most metropolitan areas are slow, inconvenient, and lack sufficient coverage to rival the automobile (Pendall et al., 2014). Whilst many researchers have argued that private vehicle ownership is associated with higher incidence of employment (Blumenberg and Pierce, 2016; Smart and Klein, 2018), the costs of owning and maintaining a car may be greater than the income gains associated with car ownership. Low-income buyers are least likely to get the best prices while buying cars.

Unpacking Mental Health among Women

The US economy defines an "ideal worker" as a male full-time worker who puts in the hours no matter what and is willing to relocate if necessary (Williams, 2004). Naturally, a female is needed to assist this "ideal worker" to shine (Cerrato and Cifre, 2018; Woods and Eagly, 2015). Unfortunately, such expectations causes work-family conflict and stress. The notion that women stand up to stress better than men appear to mean that women can perform the lion's share of domestic work and childcare and not feel the stress (Bianchi, 2011; Coltrane and Messino, 2000).

Almeida and Kessler (1998) developed a personal interview to assess the occurrence of daily stressors called the Daily Inventory of Stressful Events (DISE). Almeida et al. (2020) used 2010 DISE on the U.S. National sample of adults aged 25-74 ($N = 1031$), to determine the prevalence as well correlates of daily stressors. Women had more frequent days in which they reported one stressful event, $t(1030) = 5.1$, $P < .01$ and reported higher levels of physical symptoms, $t(1030) = 3.9$, $P < .01$.

The magnitude and types of stressors that women face is different. Torquati et al. (2019) included seven longitudinal studies, with 28,431 unique participants to find out if shift work was associated with an increased overall risk of adverse mental health outcomes. They found that female shift workers were more likely to experience depressive symptoms than female non-shift workers (odds

ratio = 1.73; 95% CI = 1.39, 2.14). In 2019, the World Health Organization (WHO) recognized burnout as a syndrome linked to chronic stress at work. Burnout is commonly defined as Malach's triad of emotional exhaustion, depersonalization or cynicism, and feelings of diminished personal accomplishment in the context of the work environment (Malach-Pines, 2005).

The consequences of work-home conflict and their impact on depression have been reported as early as 6 months into the first postgraduate year and are more common among women physicians than among men (Guille et al., 2017). Women physicians employed full time spend 8.5 additional hours per week on child care and other domestic activities, including care for elderly parents (Jolly et al., 2014).

Improved technology has made working from home more attractive but the line between family and work have diffused producing work-family conflict (WFC) which is considered as a psychosocial risks (Cerrato and Cifre, 2018). WFC negatively affects both health and general life such as work performance and work satisfaction and also decreases family satisfaction (Cerrato and Cifre, 2018).

Gender and Well-Being Studies

Well-being refers to optimal psychological experience and functioning (Stevenson and Wolfers, 2009). A significant body of research has used Diener and Emmon's (1984) Subjective Well-Being (SWB) and Ryff's (1989) research on Psychological Well-Being (Huppert, 2009; Ryan and Deci, 2006). Subjective Well-Being scales have also been used to identify whether the commute to work has an impact on the SWB of workers (Choi et al., 2013; Ettema et al., 2010, 2012; Novaco and Gonzalez, 2009). These studies have shown that commuting has not increased happiness for men and women, but it adversely affects the women's well-being even more so. Women make decisions about commuting under a different set of constraints than men, and commuting takes away time from competing demand of trip-chaining and day-time fixity constraints (drop-off and pick-up). Employers fail to recognize how the commute affects staff differently according to their life situation (Roberts et al., 2011).

Stevenson and Wolfer examined men's and women's subjective well-being in the United States over 35 years using data from the General Social Survey (GSS). This survey is a nationally representative sample of about 4500 respondents since 1972. The authors found happiness greater for men relative to women. This finding of a decline in women's well-being relative to that of men, raises questions about whether modern social constructs (work and life) have made women worse off.

Social exclusion is often misunderstood, poorly defined and poorly measured although a key determinant of psychological well-being of single parents, elderly in poverty, unemployed, and immigrants (Santana, 2002). Social exclusion refers to a disadvantage, cause by consequences such as the absence of transport to enable personal mobility and affects individuals and groups who are denied access to the goods, services, activities, and resources (Social Exclusion Unit, 2003; Sen, 2000). Research has shown that increasing trip making and improving a person's social capital and sense of community is likely to reduce risks of social exclusion and increase wellbeing (Lucas, 2012).

Importance of Activity Models in Improving Gendered Mobility

Activity-based models and the study of entire trip chains became the focus of model development in the 1990s (Misra and Bhat, 2000). The activity-based travel demand analysis viewed travel as a derived demand to complete household activities (Axhausen and Gärling, 1992). Activity-based travel research has received much attention from travel demand modelers because they best capture complex travel episodes, such as multipurpose and multistep travel (Bhat and Koppelman, 2003; McNally and Rindt, 2008). The five important features include:

1. Travel derived from activity participation;
2. Activity-based approach that focuses on sequences of patterns of activities;
3. Individual's activity both planned and executed in the household (family) context;
4. Activities spread throughout a 24-hour period in a continuous manner, rather than discrete events;
5. Travel and location choices could be constrained (work, picking up, school) or unconstrained (shopping and leisure) (Chu et al., 2012)

Activity-based travel modelers have broadened the data collection adding new dimensions to include nonworkers. Misra and Bhat (2000) analyzed weekday activity travel data of 1190 nonworkers with 2327 individuals with at least one out of home activity for the city of San Francisco. The mean age was 57.5 (SD = 17.7), mostly Caucasian and slightly higher number of females. The study was important because it was one of the first to analyze the activity patterns of the nonworking households. Their exploratory analysis corroborated some of the earlier findings on activity sequencing while adding a better understanding of the activity patterns of older couples.

The activity-based modeling has the potential to be robust indicators of socio-economic health of the workers and nonworkers. Indeed social exclusion and material deprivation should be important components of any activity-based models that looks at gender differences. Transportation researchers have begun to include nonwork trips and trip chaining in their analysis and have found that women continue to do complex non-work trips, unfortunately, many of these trips still remain invisible as the data often remains uncaptured and there have not been enough interest to look at intra-gender differences in activity based modeling (Susilo et al., 2012; Uteng and Cresswell, 2012).

Discussion

Feminist transportation planners are becoming increasingly aware that “gendered mobility” affects women’s economic mobility, career choices and psychological well-being. Women make up almost half of the workforce, and a record 40% are breadwinners for their families. According to the 2018 US Census, workers in female-householder families (mostly African-Americans and Hispanics) worked full-time, year-round at a greater rate. And, women continue to be over-represented in occupational roles that allow flexibility, such as customer service, healthcare, and counseling occupations, where they are faced with emotionally charged encounters where they have to remain reserved (Glomb and Tews, 2004; Hochschild, 1989). And, yet, transportation agencies and policy makers have not made it a priority. In 2014, the Planning and Women Division of the American Planning Association (APA) and the Women’s Planning Forum of Cornell University, surveyed 300 local governments to ask about whether plans account for the needs of women. The overwhelming majority (98%) responded that they do not (Khanna, 2002). Gender issues have been least accommodated in transit planning although women are the predominant users (Loukaitou-Sideris et al., 2002; Metro, 2019; McLafferty and Preston, 1991).

There is a desperate need to spend time and understand what is truly expected of each woman to accomplish her work every day, both as a worker and as a mother in many cases. There are still a considerable number of questions as to the issues of why women “opt-out” of careers. Why are employers unwilling to give flexible working to women? Why women are cautious about choosing flex schedule? Why female doctors who graduate at the same rate as the men then opt for fewer hours? The OECD (2014) study showed that in every country, men are able to fit in valuable extra minutes of leisure each day while women spend more time doing unpaid housework.

Emotional labor demands have effects on career mobility, occupational segregation, poor job security and satisfaction, wage gap stress and well-being. As mentioned earlier, low wages make women responsible for more housework, childcare and emotional work at home and men can “buy” out time by getting higher pay. Women continue to make decisions about commuting under different set of constraints than men and it becomes a self-fulfilling cycle of seeking part-time or low paying jobs (Brines, 1994; Erickson, 2005). Commuting takes away time from competing demands, and women opt for shorter commutes and lower bargaining power (Chatterjee, 2019).

In 2001, the gap between the number of miles driven by men and women were considerably higher for all age groups (Fig. 4A), this dropped by 2017 but men still drive more miles for all age groups (Fig. 4B). There is a need of a better understanding of these numbers and find out whether these numbers translate into fewer opportunities in career, social exclusion, material deprivation and adverse mental health outcomes for women.

Women have to negotiate cultural constructs of family responsibilities and more recently, neurosexism (Fine, 2008) where working mothers struggle against the natural wiring of female brains to be the caregivers. The tug of war between career circuits and maternal circuits increase stress and anxiety and diminishes brainpower for mothering (Brizendine, 2007; as explained by Fine, 2008).

Figure 4 (Continued)

Conclusion

There is a lot to be done to first address the data gap and to instill in transportation researchers that gender is crosscutting. There is also the need for researchers to start questioning whether they should design research to change policies and infrastructure that perpetuate gender bias and stereotypes.

Introduction to Transport Planning

Transport systems are inherently complex because they affect the social, economic, and environmental dimensions of a territorial community, with several impacts and feedbacks not easy to be foreseen (see, e.g., the Braess paradox, [Steinberg and Zangwill, 1983](#)). Further complexity is added by the procedures needed for the construction and operation of transport systems, and mostly for the many actors involved with often conflicting interests ([Le Pira, 2018](#)). Public Administrations, at the different territorial levels (national, regional, and local) are responsible of decisions regarding the transport system. This is usually done through a set of documents that constitute a Transport Plan. It has the main objective to address the management of a sequence of decisions and actions about infrastructures, operation, and regulations of the overall transport system and their impacts on the community and the environment. Transport planning is a decision-making process based on rationality, aimed at defining and implementing transport system operations ([Ortúzar and Willumsen, 2011](#)). It is meant to effectively achieve aims and objectives as a result of a technical and political process, through a set of decisions that will inevitably favor some interests and expectations at the expense of others. It is also easy to understand why transport planning is not just about writing a plan with long-term decisions, but it is a rather dynamic process, for example, a sequence of elaborations (plans or individual projects) aimed at different decisions made in different moments.

Mathematical models play a crucial role, through their capability to simulate the transport system impacts and performances under different scenarios and, in the end, to assist the decision-maker during the planning process. Models must be considered just as tools to support the planning process, but they cannot substitute it ([Ortúzar and Willumsen, 2011](#)). The traditional planning process can be subdivided in macro-activities that can be categorized in technical and decision activities on one side, and analytical and modeling parallel phases (functional to the previous ones) on the other. Starting from the definition of the objectives and constraints, the analysis of the transport demand and supply and the traffic counts, in the present situation, are used to set up and calibrate a simulation model of the transport system. The model is then used to simulate users' behavior and vehicle flows on the different components of the transport network and predict the impacts of alternative plans and projects, under different scenarios. The outcome of the models forms the basis for decision-making. By comparing the results obtained from the model and from technical assessments (evaluation phase), a final choice is made, and the process must be followed up by an adequate monitoring of the plan.

Transport planning is losing its simple function of a rational choice among technical alternatives and is more and more being included within the policy process. In this respect, even if a transport plan is meant to increase the net welfare of a community, the benefits will never be equally distributed among its different actors and groups. Transport planning is therefore mostly about managing the public decision-making process. Besides, advances in new information and communication technologies (ICT) are rapidly changing the way transport systems and mobility are conceived, especially at the urban level. The concept of "smart city" becomes fundamental in a modern society: the "smart city of the future," that is, "a city in which ICT is merged with traditional infrastructures, coordinated and integrated using new digital technologies" ([Batty et al., 2012](#)), should be characterized by services which allow to optimize trips and to facilitate everyday activities (see e.g., the debate around "Mobility as a Service"), thus efficient transport systems are fundamental. This should be coupled with the goal of "sustainable mobility", which has been hindered by car dependence and the increased decentralization of cities, and which requires actions to reduce the need to travel and trip lengths, to

$$f = A F = A P (C) d = A P (A^T c) d$$

Figure 1 Framework for mobility analysis.

encourage modal shift and greater efficiency in the transport system (Banister, 2008). In this respect, the emergence of Sustainable Urban Mobility Plans (SUMP) has created a new direction for planning in Europe.

All these issues pose several challenges to policy-making and planning and point to the need for models capable of aiding decision-making. In this respect, research is abundant. However, the gap between model sophistication and user-friendliness is still too wide, especially considering the importance of involving non-expert citizens and stakeholders in increasingly participatory transport planning processes.

This chapter aims to provide an overview of the main approaches to modeling and simulation for transport planning and underline future research and practice-ready directions.

Models and Simulation for Transport Planning

Models and simulation tools have been developed to forecast future traffic conditions on transport networks, compare scenarios of alternative transport plans or projects, and estimate the impact of traffic or travel demand management strategies. Transport systems have been traditionally studied as the result of interaction between two main components, that is, the demand (users' trip flows – passengers or freight – per time unit) and the supply (infrastructure networks and related costs). The fundamentals of transport modeling were developed in the United States during the 1950s and later on imported into the United Kingdom in the early 1960s, following an evolutionary approach rather than revolutionary, as clearly explained in the “Handbook of Transport Modelling” by Hensher and Button (2008)^a.

Demand is usually represented via an OD (origin-destination) matrix, reproducing all the trips made in a given study area, appropriately divided into a discrete number of (internal/external) traffic zones. Supply is modeled as a mathematical representation of a network composed of nodes and weighted links, according to their fixed or variable (flow-dependent) costs, leading to respectively uncongested or congested networks.

Behavioral models are typically used to model transport demand, while graph theory is used to reproduce supply. The four-step model (FSM) is widely used to study transport demand and its interaction with supply, especially at the urban level. FSM is based on four sequential sub models: (1) trip generation, (2) trip distribution, (3) mode choice, and (4) route choice. Each one reproduces a traveler different decision, that is to perform a trip from a given origin, to which destination, by which transport mode, and route, all to choose from a set of alternatives available to him/her. Since the first two usually reproduce long term decisions linked to land use patterns (e.g., home-to-work trips), they are modeled via statistical descriptive models. On the contrary, mode and route choices are highly dependent on individual behaviors that can vary according to the state of the system. This is why behavioral models are used to reproduce these two choices. The economic analysis of discrete individual choices makes use of random utility maximization models (Block and Marschak, 1959). Discrete choice models (DCM) are basically econometric models aimed at analysing the behavior of a decision-maker when choosing among different (discrete) alternatives, assuming a rational decision-maker that tends to maximize his/her own utility. Varying model specifications leads to different models. The Multinomial Logit Model is widely used in transport planning to estimate travel demand, given a set of transport alternatives (i.e., mode choice or route choice) defined by certain attributes (Ben-Akiva and Lerman, 1985; Cascetta, 2009).

^aThe reader is encouraged to refer to this Handbook and to Ortúzar and Willumsen (2011) for a comprehensive overview of fundamental concepts of transport modelling that, for space reason and diversity of scope, cannot be covered by the present contribution.

Once the demand is known, the analysis of its interaction with the supply allows to study the performance of the transport system and the potential impacts of new scenarios. A simple scheme reproducing the different phases, methods and outputs to study the transport system of a given area is reported in **Figure 1**. Starting from a network and an OD demand, which allows to build an incidence matrix (A) accounting for the links pertaining to the alternative paths, flows in network links (f) are determined by path flows (F), which depend on the results of the route choice model, where the probability (P) of choosing a route is affected by its cost C .

Given a known travel demand distribution and transport network, traffic assignment models are used to estimate the flows on the different elements of the network and thus calculate performance indicators (times, costs, impacts on environment, etc.) consistent with the planning objectives. Most of the modeling efforts have been devoted to such tools. Traditional assignment models are homogeneous, considering only one type of user (e.g., road vehicles) and one type of network (e.g., road network). They assume that all travelers take the minimum cost route among the one available per each origin/destination pair. At same time, the cost of each route changes as a consequence of the increasing flow, until a so called user-equilibrium is reached ([Wardrop, 1952](#)), when no one can reduce his/her cost by unilaterally choosing another route. Many mathematical formulations and algorithms have been proposed and used to solve the user equilibrium problem ([Sheffi, 1985](#); [Florian and Hearn, 2003](#); [Gentile and Noekel, 2009](#)).

The vast majority of strategic transport models still uses traditional static traffic assignment (STA) procedures with travel time functions in which traffic flow can exceed capacity, delays are predicted in the wrong locations, and intersections are not properly handled ([Bliemer et al., 2013](#)). Dealing with time-varying flows both on the supply side (network costs) and demand side (OD trips' rate) is the challenge researchers face when dealing with Dynamic Traffic Assignment (DTA) in network modeling. The aim is to determine how traffic flow patterns (on links and paths) evolve over time and space in the network ([Peeta and Ziliaskoupolos, 2001](#)). The main difference with STA is that DTA models require path delay operators (to describe flow propagation in the network and queuing phenomena at intersections), rather than the monotonically increasing-with-flow path-delay function used with static assignment. This is to take into account that traveling along a path requires a given time, during which traffic conditions vary in such a way that is not predictable before departure ([Hensher and Button, 2008](#)).

Many software packages are today available to support analyses based on traffic simulations^b. They are traditionally divided into microscopic, mesoscopic and macroscopic traffic simulation, according to the level of description of vehicles and traffic flows. While attention has been traditionally paid to developing macroscopic models able to reproduce the transport system of large areas (cities, regions, and states), in the last years microscopic models have emerged as fundamental tools to increase the realism and the level of details of simulations. They are based on the description of the cinematic of each vehicle within a traffic flow, where acceleration, deceleration, speed and lane changing depend on the speed and position of the other vehicles. They also allow modeling of the behavior of individual heterogeneous components of the transport system, for example, pedestrian flows ([Helbing and Molnar, 1995](#)). More recently, macro and micro approaches have been integrated, for example, in large-scale microsimulation models like MATSIM ([Balmer et al., 2008](#)).

Limits and New Trends of Modeling and Simulation for Transport Planning

Though FSM has been used in professional practice by transport planners in the last decades, still a set of limits has to be outlined:

- *Independence assumptions.* While models are theoretically sound when considered separately, the independence assumption of the four submodels is an oversimplification required more for an easy tractability than for logical consistency.
- *The “predict and provide” paradigm.* The spatial resolution, based on the traffic analysis zone (TAZ) approach, tends to facilitate the ease of movement of motorized vehicles. Obtaining a high level of service for a road network translates into increasing the average speed of vehicles and lowering traffic intensity; this automatically determines the request for new infrastructures to increase road capacity, which consequently translates into further dependence on the use of the car. In this respect, the FSM responds to the so called “predict and provide” approach.
- *Transport supply management scenarios.* Asking for more capacity fulfils the presumptions of the dominant car culture, accepted by policy-makers and the public at large. Cost-effective alternatives are rarely proposed, and a transport supply management approach is preferred to satisfy trips generated by growth and land use; vice versa, transport demand management measures deployed to induce a change in travel behavior are less frequently considered ([Lewis, 1998](#)).
- *Multimodal network models.* A car-oriented culture and planning can lead to an inaccurate modeling of multimodal networks. Models usually account for separate OD matrices for private and public transport trips, and are hardly able to reproduce their interaction in unique simulation framework. Besides, even if research is abundant on sophisticated modeling approached to transit assignment ([De Cea and Fernández, 2007](#)), simulations used in the common practice are usually simplified and based on scheduled timetables, and are not able to readjust demand assignment taking into account real-time network conditions.
- *Trip-based travel demand modeling.* Given that different trip purposes are modeled separately, the scheduling and spatio-temporal inter-relationships between all trips and activities encompassing the individual's activity-travel pattern are not considered ([Bhat and Koppelman, 1999](#)).
-

^bThe reader can refer to the book of [Barceló \(2010\)](#) for a detailed description of most of the cited traffic simulation softwares.

Land use transport interaction. Finally, the FSM fails to consider the complex two-way dynamic link between land-use choices and the transport system (Kii et al., 2016)

It is thus important to fill the gap between modeling efforts and planning. In this respect, the role of transport modeling for urban planning has been changing from focusing on transport as a single issue to a more holistic view of mobility in relation to land use organization, environment and society as a whole, and from a relatively simple institutional context to a complex one with multiple participating stakeholders with often conflicting goals (Bertolini et al., 2008). Besides, traditional transport planning has been more focused on the passenger side, neglecting the important part played by freight transport and the potential of freight models, especially at the urban level (Tavasszy and de Jong, 2014; Gatta et al., 2017).

In the following, some of these new trends that have the potential to overcome these limitations will be briefly described.

Land Use Transport Interaction Models

Over the past 60 years, a considerable amount of research has led to operational Land Use and Transport Interaction (LUTI) models as decision support systems for assessing the impacts of land-use decisions on transport and vice versa, as well as evaluating large-scale transport investments. LUTI models integrate a Land-Use sub model and a Transport System sub model. The main aim is to integrate and predict households' residential and job location choice, the associated daily activity-travel patterns as well as transport mode and route choice (Acheampong and Silva, 2015). From the early LUTI aggregate spatial interaction-based models, drawing on the gravity analogy (Lowry, 1964), to aggregate utility-based and micro-simulation LUTI models (Kii et al., 2016), the need to capture the complex individual behavior dynamics and the relevant high resolution of spatial analysis has led to the adoption of agent-based modeling (ABM) for their capability to capture emergent phenomena (Le Pira et al., 2015). While the use of behavioral rules is similar to other disaggregate simulation techniques, ABM approaches allow agents (e.g., household members, travelers) to learn, modify, and improve their interactions with their environment.

While a FSM aims at high level of service for traffic flows and is car-oriented, LUTI models aim at increasing spatial and individual accessibility, that is the ease to reach a destination (active accessibility), and the ease for a destination to be reached (passive accessibility) (Geurs et al., 2010).

Relying on LUTI models able to predict accessibility as a proxy indicator of sustainability allows to change the transport planning paradigm from the "predict and provide" of FSMs to the "predict and prevent" approach. Planning moves from a simple reaction to provide greater infrastructural capacity to the expected growth in travel demand, to the prevention of unwanted results through proactive and prescriptive policies on the management of transport demand and land use. The natural consequence is that more and more researchers and practitioners now focus on a more balanced view of mobility and accessibility, completely encompassing the sustainable mobility paradigm (Banister, 2008).

Activity-Based Travel Demand Models

The activity-based approach recognizes travel as a derived demand from the need to pursue activities distributed in space and time. The key areas of investigation of this approach, therefore, include the demand for activity participation, the spatio-temporal constraints within which activity-travel behavior occurs, the complex interpersonal dynamics resulting from the interaction among household members and social networks, and activity scheduling and trip-chaining behavior in time and space (Bhat and Koppelman, 1999).

While trip-based models deal with aggregated units of analysis (households within a traffic zone), activity-based models are disaggregate, using a utility-econometric approach or microsimulation, for example, SimMobility (Alho et al., 2017). Research on LUTI models follows two lines: one is more flexible and complex, and involves intensive modeling at the local scale; the other involves simplified modeling at regional, national and global scales. The co-evolution of these two approaches is expected to contribute to sustainability science (Kii et al., 2016). There are a number of constraints imposed by microsimulation models. In addition to the large input data requirements, such models are slow to execute and require several running times, outputs between runs are also subject to significant stochastic variation and uncertainty (Acheampong and Silva, 2015).

Big Data for Multimodal Transport Modeling

With respect to the last point, significant opportunities come today by the widespread deployment of ICT, sensors and mobile devices (e.g., GPS, smartphones). The chance to record and collect data about traveling behaviors of individuals, position, route choice and speed of vehicles has opened a new field of research and professional practice falling under the topic "Big data and transport". In this respect, the known methods for updating an historic OD matrix by traffic detector counts and route choice behavior assumptions can benefit today of large and ubiquitous availability of Floating Car Data (Vogt et al., 2019). The explosion of "Big Data" availability together with the development of artificial intelligence techniques (e.g., machine learning) on more and more powerful computers is even questioning the need of transport modeling for traffic predictions. Real-time travel information deriving from the demand side (e.g., passenger location and desired destination), from the supply side (vehicle position and scheduled routing), coupled with GIS-based web platforms and fast effective dispatcher algorithms, have given birth to the possibility of dynamic transport planning, leading to the Mobility as a Service (MaaS) paradigm. It is a new mobility model that enables the

integration of the currently fragmented transport modes (collective, individual, public, private, and shared) and mobility services a traveler needs to conduct a trip (planning, booking, access to real time information, payment and ticketing). König et al. (2016) defined it as a multimodal and sustainable mobility service addressing customers' transport needs by integrating planning and payment on a one-stop-shop principle. Public transport should act as the backbone of this new paradigm, thus a correct planning based on multimodal network models is fundamental.

Freight Transport Models

Freight transport is an important aspect in transport planning. In this respect, increasing population, falling trade barriers, and declining transport costs fuelled by increasing consumption levels and the customisation of products and services have led to a continuous increase of freight flows (Tavasszy and de Jong, 2014). Only in recent years it became a public policy problem, mainly due to its impact on the environment and the community as a whole. Freight models have been developed in parallel with passenger models, even if at a slower pace. However, their inclusion in current transport planning practice is still lacking, due to the quite recent awareness of freight negative impacts on sustainability. Freight models can be categorized according to the levels of decisions, that is strategic, tactical and operational, which relate to three different markets, that is commodity, inventory logistics services, and transport logistics services, with direct and mutual dependence between decisions at the different layers (Tavasszy and de Jong, 2014). However, it is difficult to combine all the levels in a comprehensive model^c. Some recent attempts go in this direction, for example the MASS-GT model (de Bok and Tavasszy, 2018) or SimMobility Freight (Alho et al., 2017).

Understanding actor behavior and the consequences of their actions is fundamental in freight models. Especially at the urban level, urban freight transport poses several challenges to transport policy-making, being characterized by both public and private interests and trade-off between freight delivery efficiency and city sustainability (Gatta et al., 2017). Based on this premise, freight modeling tends to be more comprehensive and empirically sound, while also taking into account the behavioral components of the different actors and their heterogeneous preferences (Marcucci et al., 2017).

Participatory Decision-Support Models

The gap between modeling effort and planning practice is still a problem to overcome, especially if one considers the involvement of non-experts in the planning process. Besides, while there are many methods for stakeholder involvement, a deeper analysis of the underlying social dynamics is still missing and a modeling approach can be used to help the participatory process (Le Pira, 2018). In this respect, even if public participation is considered important for the success of a decision-making process, in general it is not well-structured and there is a lack of group decision-support methods and models that can guide stakeholders' involvement towards well-thought-out decisions. Le Pira et al. (2017) provide an overview of participatory decision-support methods and models, according to the desired level of engagement, from stakeholder identification and analysis to stakeholder consultation and participation in the decision-making process. These include social network analysis, multi-criteria decision-making methods, Participatory GIS, DCM, and ABM. In particular, a combination of DCM and ABM has proved to be useful to forecast stakeholders' reaction to policy change, but also to predict the outcome of an interaction process aimed at consensus building (Marcucci et al., 2017; Le Pira et al., 2017). Still, these models are still very theoretical and need to be tested in practice to verify their usability and added value to decision-making.

Conclusion

This chapter addressed the topic of modeling and simulation for transport planning, presenting the state of the art and some future research directions. After an introduction to transport planning challenges and the rationale of using models and simulations as decision-support tools, the main modeling approaches to reproduce and study transport systems have been presented. Given the limitations of traditional approaches, and the gap between research and practice, recent trends and modeling efforts have been briefly described to underline future research and practice-ready directions. To sum up, when dealing with modeling and simulation for transport planning, some fundamental concepts should be taken into consideration: (1) land use and transport interaction, (2) activity-based approach, (3) big data for transport modeling, (4) freight transport models and (5) participatory decision-support models. There are still avenues for new research, but it should be necessarily supported by planning implementation to bridge the gap between theory and practice.

Biography

Michela Le Pira is currently a Research fellow/lecturer specialized in Transport Planning at the University of Catania (Italy). She holds a PhD in transport engineering. As a PhD student, she focused on public participation in transport planning supported by agent-based modeling and multi-criteria decision methods. As a Postdoc researcher at University of Roma Tre, she worked on participatory decision-support methods for sustainable urban freight transport policy-making. As a research fellow at the University of Catania and guest researcher at TU Delft (Netherlands), she is currently investigating new mobility services for both passengers and freight.

Giuseppe Inturri is Associate Professor in Transport at the Department of Electric, Electronic and Computer Engineering at the University of Catania. He is also Rector's Delegate for the promotion of sustainable mobility and Rector's Delegate for the Italian University Network for Sustainable Development. He has research interests in land use and transport planning, sustainable mobility, multi-criteria analysis, public participation in transport decisions, agent based simulation and transport modeling. He is author of more than 80 publications in international journals, book chapters and conference proceedings.

Matteo Ignaccolo is Full Professor of Transport Planning (scientific sector ICAR/05) at the University of Catania. He teaches several Transport courses for Transport, Civil and Environmental Engineers and he is a member of the committee of the Doctorate in "Evaluation and mitigation of urban and land risks". He is author of over 100 publications on topics like: urban transport systems, sustainable mobility, air transport systems, technical/economic feasibility of transport interventions, and agent-based modeling applied to transport planning. He is currently the National President of AIIT (Italian Association for Traffic and Transport Engineering) and the Editor-in-Chief of the scientific journal "European Transport / Trasporti Europei."

Introduction

In their book, [Sinha and Labi \(2007\)](#) divide transport costs by the source of cost incurrence into: (1) *agency costs* (the ones incurred by service providers), (2) *user costs* (monetary and nonmonetary costs incurred by the consumers of the transport services, that is passengers, shippers, and truckers), and (3) *community costs*, that represent the costs incurred by the community as a whole, including entities not directly involved with the use of the facility. Any side effect of travel that generates a cost for one of these three categories may be defined as a secondary cost, or **externality**. It is important to underline that such costs are generally not borne by transport users and hence not taken into account when they make a transport decision.

[Black \(2010\)](#) states that the unsustainability margins of transport are unavoidable, and defines a sustainable transport system as “one that provides transport and mobility with renewable fuels while minimizing emissions detrimental to the local and global environment, and preventing needless fatalities, injuries, and congestion.” This definition is not exactly avant-garde, as the discussion about externalities started really with [Pigou \(1920\)](#), who developed the works by [Sidgwick \(1887\)](#) and [Marshall \(1890\)](#). It specifies, however, that externalities are inevitable within transport, and also that enlightened transport planning can only aim at their containment. Starting from the theory of [Coase \(1960\)](#), [Arrow \(1969\)](#) first explained how externalities could be internalized by the creation of additional markets. Concrete investigations have been also made in various terms of policy ([Attard and Ison, 2015](#); [Button, 1990](#); [de Palma and Lindsey, 2011](#); [Eliasson and Jonsson, 2011](#); [Eliasson, 2009](#); [Small, 1992](#)). Literature on externalities also focused on advanced modeling ([Arnott et al., 1993](#); [Hensher, 2018](#); [Hess and Scarpa, 2010](#)), modal use and concurrency ([Cavallaro et al., 2018a](#); [Mulley et al., 2017](#)), and climate change ([Cavallaro et al., 2018b](#); [Hensher, 2008](#); [Nocera and Cavallaro, 2012](#); [Nocera et al., 2018a, 2018b](#)).

As a last preliminary concept, the meaning and the possible use of the terms “externalities” and “external costs” should be cleared. External costs may be seen as the monetary valuation of externalities, as they represent the costs that are caused from mobility without being included in the price of mobility itself. For example, if someone decides to use his/her car, he/she pays for the car itself, the gasoline, the insurance, but generally neither for the air pollution, nor for the noise caused. Such costs of mobility must be borne by others, and are defined “external” for this reason.

Both external costs and externalities share some important properties, and for this reason they are often used as synonyms in literature ([Bigazzi and Figliozzi, 2013](#); [Bigazzi and Figliozzi, 2013](#); [Lindsey et al., 2019](#); [Lindsey et al., 2019](#)). First of all, they both refer to side effects of transport. Furthermore, and most importantly: as specified above already, they represent real costs not included in the market price of transport and not borne by the users. For this reason, the implementation of a sort of compensation—generally under the form of a tax or a subsidy—should be required for economic efficiency to be achieved. Since such compensation is often not included, externalities prevent the accomplishment of the perfect concurrency. This pushes away the system from economic efficiency, opening up the possibility for second-best solutions, which have thoroughly been discussed in mathematical terms by [Verhoef \(2000\)](#) and [Proost \(2011\)](#), and particularly in association with externalities by a large number of authors (among many others, [Button, 2006](#); [Diamond, 1973](#); [Tikoudis et al., 2018](#)).

Main Negative Externalities in Transport

The main negative externalities of transport concern the traffic accidents, air pollution, climate change, noise and congestion, and are described in [Table 1](#).

There is no universal agreement in the literature on what lies aside of the contents of [Table 1](#). According to [Sinha and Labi \(2007\)](#), [DeLucchi and McCubbin \(2011\)](#), [Friedrich and Quinet \(2011\)](#), other externalities may include visibility, agriculture, materials, forestry and soil, water, energy, and landscape.

Congestion is the impedance that vehicles impose on each other, due to speed–flow relationships, in conditions where the use of the transport system approaches its capacity ([European Conference of Ministers of Transport ECMT, 2000](#)). As the flow of vehicles

Table 1 Most commonly considered external costs in transport planning

	Source	Public abatement	Nature of external cost	Policy instrument used
Congestion	Too many users of the same facilities increase in-vehicle cost and schedule delay cost	Increase of capacity, use of ITS	Mainly time and schedule delay costs	Congestion pricing, gasoline taxes, regulation
Traffic accidents	More intensive or more mixed use influences the average probability and severity of accidents	Adaptation of road equipment, emergency services, etc.	Mainly health, loss of life, material damage	Traffic regulations, pricing to reduce demand
Air pollution	Exhaust of combustion engines (car, trucks, bus, airplane, power stations)		Mainly health, loss of life	Standards on car emissions and quality of fuels
Noise	Vehicle, airplanes, trains	Noise walls, more silent road surfaces, tire design	Discomfort, health	Standards on car, banning use of certain equipment at night Tradable permits for night flights
Climate change	Fossil fuel use by vehicles, diesel-fuel-powered trains, airplanes		Long-term disruption of climate (sea level, cooling costs, water supply etc.)	Standards on fuel consumption (minimum efficiency) CO ₂ taxes Tradable permits

Source: Modified from Proost (2011).

on a given road increases, from a certain threshold value each additional vehicle is not only operating at an ever higher private cost, but it also causes an increase in the cost to other vehicles already in circulation (Danielis, 2001). In this sense, congestion is an externality internal to the examined transport modality and not *primarily* affecting the community. However, there is an interdependence between congestion and other externalities. For example, it decreases the energy efficiency of engines and, consequently, it increases air pollution. At the same time, the severity of the accidents is reduced, but their quantity increases, thus posing (still open) issues about the relationship between congestion and accident risks (Ricardo-AEA, 2014). The Roadway Congestion Index (Schrank and Thomas, 2009) can be a valid tool to calculate it for specific areas.

External accident costs do not refer to the entire costs derived from a generic crash, but include only the part that is not covered by risk-oriented insurance premiums. Thus, the calculation of the external component is a function of the level of accidents, but also of the insurance system: a rough distinction includes fatal, injury and property-damage-only crashes (Sinha and Labi, 2007). According to Ricardo-AEA (2014), categories related to accident include “medical costs, production losses, material damages and administrative costs, and the risk value as a proxy to estimate pain, grief and suffering caused by traffic accidents in monetary values.” These can be calculated as the sum of the expected cost due to an accident for the persons exposed to risk, the accident cost for the rest of the society (output loss, material costs, police and medical costs) and the expected cost for the relatives and friends of the persons exposed to risk. When referring to external costs, the last category is mostly considered. The evaluation of accident costs can be based on contingent valuations, which assess the willingness to pay for safety by transport users.

Air pollution refers to the presence of toxic chemicals or compounds in the air, at levels that can be health threatening. Such compounds may be found either in a gaseous form or in a solid form (as particulate matter suspended in the air). *Criteria Air Pollutants* represent the main air pollutants. Black (2011) includes in this category carbon monoxide (CO), nitrogen oxide (NO_x), particulate matter of size 10 µm or less (PM₁₀), sulfur dioxide (SO₂), lead (Pb), and Ozone (O₃). Sinha and Labi (2007) present a slightly different list, inserting also particulate matter of size 2.5 µm or less (PM_{2.5}), volatile organic compounds (VOCs) and ammonia (NH₃). The quantification of their emission in the atmosphere is function of several factors, which include the characteristics of the travel (e.g., the speed), the facility (e.g., the type of infrastructure and its status of maintenance), the driver and his/her behaviors, the vehicle (e.g., size or maintenance) and the environment (including temperature and humidity). Typically, effects of air pollution can be evaluated by adopting the dose–response method: this method focuses on the quantification of the impact that the emissions have on human health, environment and economic activities, calculated for the population potentially affected by the phenomenon.

Noise is an externality harmful to human health in at least two different ways. Indeed, it may produce psychological consequences (resulting in annoyance, nervousness and behavioral disorders), or physiological ones, resulting in long-term impacts such as hypertension and myocardial infarction. Impacts can vary significantly, being functions of several factors such as duration, frequency and intensity of the noise. Specific indicators have been introduced, in order to make this comparable. Day-evening-night level (L_{den}) is a main descriptor of noise level based on energy equivalent noise level (L_{eq}) over a whole day with a penalty of 10 dB (A) for night time noise (23.00–7.00) and an additional penalty of 5 dB(A) for evening noise (European Environmental Agency, 2001). Noise can be evaluated by adopting the hedonic pricing method, but due to its numerous and well-known limitations (Arguea and Hsiao, 1993), this may be integrated with other evaluations, such as the avoidance cost or the contingent valuation method.

Table 2 Methods to assign an economic value to transport externalities

Externality	Methods to assign an economic value
Congestion	Travel time delay, Contingent valuation method
Accident	Contingent valuation method, Dose/response assessment, Hedonic prices
Air pollution	Dose/response assessment, Avoidance cost, Contingent valuation method, Hedonic prices
Noise	Contingent valuation method, Hedonic Pricing Method, Avoidance cost, Dose/response assessment
Climate change	Damage costs, Avoidance costs

Sources: Danielis, 2001; Transportation Research Board, 2001; Ricardo-AEA, 2014.

Climate change can be defined as a change in the pattern of weather, and related changes in oceans, land surfaces and ice sheets, occurring over time scales of decades or longer (Australian Academy of Science, 2019). According to recent estimations (EC, 2019), it constitutes about 15% of transport externalities at the EU level, but its share is growing. Greenhouse gases (GHGs) are responsible for the greenhouse effect, a phenomenon through which the atmosphere absorbs the infrared radiation emitted by the planet's surface as a result of exposure to solar radiation, thus increasing the mean temperature of the planet. GHGs include carbon dioxide (CO₂), methane (CH₄), nitrous oxides (N₂O), ozone (O₃), and fluorinated gases (F-gases). Their internalization in transport costs is object of much debate (Nocera and Cavallaro, 2014). Prices determined by carbon trading or by carbon tax cannot be considered representative: high volatility and price fluctuations make the former unsuitable for long-term forecasts (Ellerman et al., 2008), whereas the latter depends on political choices. Alternative techniques such as the *damage costs* and the *avoidance costs* methods are preferred (Clarkson and Deyes, 2002). *Damage costs* assesses the future physical impacts of climate change and link them with their effects on the economy and society. *Avoidance costs* quantifies the money required to avoid an increase of GHG levels, to reduce such emissions or to remove GHG from the atmosphere.

Each of the externality previously presented can be internalized in transport costs by the assignment of a fair unitary economic value—a point that will be more specifically covered in Section 4. **Table 2** summarizes the methods for this specific aim.

Positive Externalities in Transport

The question of whether transport may yield also important external benefits should have a clear positive answer, even if this concept can be amplified by some parties when it comes to a comparison with external costs: frequent air travelers may for instance claim that the external benefits of air transport largely exceed its external costs, thus casting doubt on the necessity to restrict airplane use.

This point will not be discussed into detail. It should be, however, beyond dispute that contemporary societies are largely influenced by transport, inducing added value and employment in several fields. Besides the negative externalities mentioned in the previous section, it should hence be added that the different positive aspects are indeed benefits for society (Verhoef, 1994).

As a general concept, positive externalities of transport networks may include the ability to provide emergency services, increases in land value due to improved accessibility, and general agglomeration benefits. The last point is explained brilliantly in de Palma et al. (2019). The creation of value for some public areas efficiently served by public transport can also be interpreted as a positive social consequence of the improvement of accessibility. It is not exactly undisputed, but a positive correlation between real-estate property values and transport is generally acknowledged in literature: Efthymiou and Antoniou (2013) show that proximity to transport infrastructure has a direct impact on house purchase prices and rents, which is either positive or negative depending on the type of the transport system. Landis et al. (1995), Benjamin and Sirmins (1996), and Welch et al. (2016) also highlight a potential value of efficient transport systems, while negative effects on real-estate value have been reported by Chen et al. (1998) and Gadziński and Radzinski (2016).

Other positive externalities include the so-called “Mohring effect” (Mohring, 1972): it is the observation that urban public transport exhibits considerable economies of scale if users' waiting time is included in the cost function. Because waiting time forms part of the costs of transport, the Mohring effect implies increasing returns to scale for scheduled urban transport services and brings with it the implication that without subsidization, frequencies will be lower than socially optimal.

The quantification of those positive impacts is not straightforward, as the valuation techniques employed may often yield biased estimates (see section 4 for details). Legaspi et al. (2015) developed a practical framework for estimating the wider economic benefits generated from transport investments, while Ignaccolo et al. (2016) examined the potential impact of land use and transport policies on external costs through the evaluation of a simple ideal indicator. They report that high-density urban areas, close destinations and accessible with a broad spectrum of opportunities for low-impact transport (public transport, cycling, walking), reduce environmental impacts and transport externalities.

Economic Evaluation of Externalities

There is a keen interest in determining the overall costs and benefits of transport, hence including also externalities in the context. While it is taken for granted that transport has considerable repercussions of environmental and social nature, opinions strongly

diverge when it comes to the conceptual definition of external benefit and cost, to their identification in the case of transport, and especially to their monetary quantification.

A first difficulty derives from the fact that there is a univocal unit of measurement only for some impacts (land consumption, number of people involved in accidents, noise, vibrations, and so on). Other impacts may have no aggregate unit of measurement (air, water, and soil pollution), or strongly rely upon subjective perceptions (visual impacts).

Furthermore, there are time differences between the manifestation of damage and its perception. Damages can be immediate, short-term (noise, visual impacts, bad smells, dust), or medium–long term (respiratory diseases and genetic alterations linked to air and water pollution). The farther the effect is, the greater the difficulty of estimating its economic value.

The spatial dimension of the environmental impacts of transport is also very diversified. A significant part of the impacts is concentrated in the surroundings of the area in which the transport activity takes place and is located precisely (noise, visual impacts, vibrations, bad smells, and the most pollutants), while other impacts cover more ground (smog, acid rain, tropospheric ozone) or are even global (ozone layer reduction, greenhouse effects). The uncertainties connected to the complex and sometimes imprecise temporal and spatial definitions of the impacts also add to the scientific uncertainties on the definition of the relationship between exposure to pollution and effects on health, on human psychology and on ecological balance.

Having taken note of the above, literature shows that the main methods for estimating the environmental value are the following ones:

1. **Dose–response method** requires information on the effect that a change in a particular chemical or pollutant has on the level of the consumer's utility (Lu et al., 2019; Pearce and Turner, 1990);
2. **Contingent valuation** elicits information on willingness to pay or willingness to accept compensation for an increase or decrease in some usually nonmarketed goods or services (Bravo-Moncayo et al., 2017; Pethig, 1994);
3. **The Hedonic price method** is based on the underlying assumption that the price of a property is related to the stream of benefits derived from it. The method relies on the hypothesis that the prices which individuals pay for commodities reflect both environmental and nonenvironmental characteristics. The implicit prices are sometimes referred to as hedonic prices, which relate to the environmental attributes of the property (Braden and Kolstad, 1991; Seo et al., 2014);
4. **The Travel-Cost method** is a widely used surrogate market approach that relies on information on time and travel costs to derive a demand curve for a recreational site. This curve is in turn used to estimate the consumers' surplus or value of the site to all users (Hanauer and Reid, 2017; Zhang et al., 2015);
5. **The Avoidance Cost approach** (also known as mitigation or control cost) quantifies the money required to avoid a certain environmental damage (Hanley and Splash, 1993; Harper et al., 2016);
6. **The Damage Cost method** assesses the future physical impacts of a certain external effect and links them with their effects on the economy and society (Maibach et al., 2008; Massiani, 2015).

It is not possible to prove that a method is in all cases better than all the others, but some criteria (theoretical reliability, repeatability of the results, comparability with other estimates) can be established to evaluate its constancy. The choice of the method will then mainly depend on the type of externality to be evaluated, on the available data, on the level of information of the user, on the financial resources and on time availability.

Given the above and in the light of the context expressed earlier in Section 2, the so-called intersectoral externalities (i.e., those regarding only the producers or the users of a certain transport service) are mainly evaluated through market prices (even if some not univocally), often using the damage cost method: gains in excess of fuel and lubricants due to congestion to be paid by car drivers belong to this category, as well as nonrefunded acts of vandalism on transit vehicles, and losses in time for passengers. This latter point is a very complicated issue: over the past five decades numerous studies have been carried out, providing substantial insights on its impact, generally with the aim of ensuring consistency and good practice in project appraisal (Abrantes and Wardman, 2011; Carrion and Levinson, 2012; Peer et al., 2014).

Environmental externalities (i.e., those borne from the community) can be divided into two further categories. In the first one, it is possible to obtain with relative ease the duration and the costs of the interventions necessary to eliminate the negative effects. The economic estimation of these externalities is strongly linked to market prices and can hence be obtained almost univocally through avoidance costs (even if sometimes, damage costs can be also used). For example, the traffic noise on a railway line belongs to this category, if it is possible to eliminate it with opportune mitigation works, that is noise barriers. Avoidance cost method estimates potential expenditures on damage avoidance or protection (Phaneuf and Requate, 2016).

A different situation occurs where the economic estimation cannot be obtained univocally, but needs models or speculations that incorporate a huge degree of uncertainty and/or may properly leave substantial room to the beliefs of the analysts. The estimations of traffic incidents to vehicles made by insurance companies belongs to this category, as well as the estimations of future climate damages. In this case, the estimation is made upon market prices, but incorporates large subjective beliefs as well, so that a fair estimation of the externality cannot be obtained univocally. The use of indicators is recommended in this case, even if the damage cost method can be used in some borderline situations.

A last category refers to the externalities not of pure consumption but referred to the ecology, the landscape and generally to the aesthetic-cultural components. These are defined as “cultural externalities” and are generally only captured by that component of the community, which relies on its cultural and skill profile. Based on all these considerations, externalities may be clustered under the scheme shown in Table 3.

Table 3 A basic taxonomy for the externalities in transport

	<i>Actors involved</i>	<i>Description</i>	<i>Methods mostly used for the internalization</i>	<i>Examples</i>
Intersectoral externalities	Producers or the users of a certain transport service	Their value refers generally directly to market transactions	Damage costs	Congestion, noise, accidents
Environmental externalities	Community	It is possible to estimate in monetary terms the costs necessary to eliminate the effects caused by the externalities The estimation cannot be obtained straightforwardly but needs models or speculations that incorporate a huge degree of uncertainty and/or may properly leave substantial room to the beliefs of the analysts	Avoidance costs. Sometimes, damage costs Indicators. Damage costs	Noise Accidents, Climate change
Cultural externalities	Community	They cannot be quantified in monetary terms, but only through ordinal scales		

It should be finally noted that most of the taxonomies referred to externalities may be tenuous, as the same impact can concern more than one category previously defined. For instance, the impact caused by a vehicle into action on an urban congested road in a historical center causes at the same time: (1) increased consumption of fuel and lubricants, whose external costs may be easily calculated through market transactions; (2) some externalities (i.e., noise) for which the external costs may be calculated by planning and computing the monetary value of the works required for impact mitigation—even though this is not always possible; (3) emission of primary pollutants that can impact on the health of the community, and whose impact can be calculated only through parameters and models; (4) carbon and methane pollution, that impact on climate change, and are an externality in the literal sense of the word; (5) some other externalities, such as visual intrusion and, once again, emission of primary pollutants that can alter the landscape and cause damage to historical buildings.

Conclusions

This chapter has discussed the concepts of externality and external costs in transport planning. On the negative side of the coin, both of them contradict the polluter-pays principle: individuals who do not benefit from an activity have to bear (part of) its costs. This is not only unfair; but also it leads to market distortions and inefficient market outcomes. In spite of these acknowledged negative consequences, externalities are widespread, especially those resulting from transport onto the environment, and tend to overshadow the positive consequences of mobility.

Methods to quantify externalities may be rather complex and do not always produce satisfactory results, due to the huge degree of uncertainty that generally affects the process. This statement is generally valid, but the case of GHG emissions is emblematic: here, unitary values of a ton of CO_{2eq} present a range up to six orders of magnitude (Nocera and Tonin, 2014). Far from being a limitation for a correct appraisal of such externalities, this point should be rather a stimulus to reduce the uncertainties in the definition of fair unitary values.

Finally, effective policies will have a decisive role to play when it comes to ensuring that scarce public funds are channeled towards clean and future-proof transport solutions. Particularly, the implementation of more efficient and alternative transport forms will be central to reducing the negative consequences of transport, in parallel with demand measures to foster a modal shift toward active, shared and public mobility. A more environmental-friendly organization of the entire mobility system will be needed to reach the goals of sustainability and climate change. This, rather than a more difficult objective of reducing mobility volumes, might be a more realistic option for society.

TNC Transport network company (Uber-like systems)

Introduction

The objective of this article is to give the reader an overview of possible applications of automated vehicles (AVs) technology within the scope of public transport (PT) systems planning and operations. This shall include shared automated vehicles (SAVs) as well. Given the initial state of development of these services, it is naturally not possible to present consolidated knowledge about their application, let alone on the impacts of these systems since they are mostly being tested in pilot studies as of the past few years. Nevertheless, it is already possible to disclose some of their applications and point out several advantages and disadvantages given the modeling studies and pilot testing. The article is not meant to be a literature review on the topic, but it does resort to relevant literature when this supports some of the planning challenges and opportunities of using AVs as PT avoiding merely speculating around the topic. In this article, we will be considering Level 4 and Level 5 automation levels as reference according to the SAE definition of automation (SAE International, 2016) meaning that vehicles can drive themselves without any need for a human driver either in all operational design domains (ODDs) (Level 5) or a specific ODD (Level 4). This does not preclude the fact that currently in most of the pilots, there is the requirement for the presence of a steward on board. The article is focused on road transport, leaving aside driverless trains or metro systems (Grogan, 2012) or drones, which are more associated with logistic systems (Kunze, 2016). One does not intend to estimate the time at which these systems will be fully matured for regular operation in our cities, this is still subject to controversy and high uncertainty (Nieuwenhuijsen et al., 2018).

Research and applications in the field of automated driving have been advancing quite fast, especially in the past 5 years (Ainsalu et al., 2018; de Almeida Correia et al., 2018), which has much to do with the moment that Google started spreading the word about their Google car project. The so-called Firefly car, built just for studying AVs, was unveiled in 2014. However, before that, there have been decades of technological development that led to the possibility of transforming dreams into reality. There are many studies related to the technology of the vehicles focused on obstacle detection and vehicle motion (Katrakazas et al., 2015), but also on studying traffic flows performance with AVs, specifically at analyzing the capacity gains with automation and connectivity (cooperation between vehicles) (van Arem and Tsao, 1997; Schakel et al., 2010). Nevertheless, this article is not intended to look at the technology challenges of vehicle automation but rather to look at their potential application and impacts in PT systems and how to plan for these.

In traditional PT systems, namely, bus systems, there is an interest in automation with a view to increasing flexibility in routing and pathfinding as well as to save personnel costs (Winter et al., 2018), specifically drivers, which account for up to 70% of PT operational costs (Currie, 2018). With the lower costs, in a future stage where the vehicles themselves are not too expensive, it would

be possible to cover more areas and eventually increasing equity in the accessibility of different regions. Moreover, without the drivers, it is much easier to adapt the service to the existing demand and not be hindered by drivers' working conditions, namely, shifts (Alessandrini et al., 2014). There are nowadays many pilots being run with vehicles that are called pods, with only a few seats, which are supplied by specialized companies aiming at testing the concept and also at making a profit out of the wish of cities and regions to join the movement. For an overview of many of these pilots, the reader may consult (Ainsalu et al., 2018).

It is also possible to observe great interest in SAV systems, which come fostered by the great growth of transport network companies (TNCs) such as Uber and Lyft. These are demand responsive and tackle some of the limitations of traditional PT (Boesch et al., 2016; Fagnant and Kockelman, 2018; Martinez et al., 2014; Scheltes and Correia, 2017). At the same time automation comes with the promise of facilitating several of the daily operations of carsharing, namely, relocating vehicles between different areas of a city, since current carsharing companies have considerable costs moving those vehicles around with drivers (Kek et al., 2009). This will represent a merging between TNCs and carsharing systems, since there will be no way of differentiating them.

In the following sections of this article, the different PT AV systems are defined along with their envisioned applications based on state of the art research and on the state of the world. In several cases, there are real systems in operation, which can help shed some light on the potential impacts of using AVs for providing PT, particularly in urban regions. We focus on planning issues for this technology aiming at exploring the challenges and opportunities, especially for cities. Planning for AVs is a very recent challenge with most of the cities not having any strategy for this future; however, some cities have started a debate for planning for automation. Moreover, there are lessons learned, both from research and applications, that can help set some recommendations for future planning of PT systems with AVs and clarify concepts for the reader who is interested in this field.

The article is structured in the following way. In the next section, the main applications of vehicle automation in PT are presented, which also includes the connection to the private usage of AVs. This continues with a section that explores what cities mostly want as an application of AVs in their mobility systems. The next section focusses on presenting expected impacts from AV application as PT. This is followed by presenting some guidelines for answering some key questions of cities on how to plan for AVs. The chapter ends with the main conclusions that can be drawn from the article.

Applications of Vehicle Automation in Public Transport

In this article, we propose to distinguish between what can be called regular service, but also on-demand, bus services with AVs, and shared mobility systems with AVs (SAV systems). However, it should be noted that such distinction is becoming quite blurred as TNCs such as Uber (cars) and ViaVan (vans) are essentially supplying the same type of service to their users, which is basically on-demand highly flexible transport services that are door-to-door and take advantage of information technology available through smartphones.

Regardless of the possibility of such systems merging due to similarity of operations, studies, and pilots, as referred in the introduction, have been organized between looking at vans (small buses or pods) and cars as the main vehicle to provide PT with automation on the roads. Usually the former is associated with only one part of the trip such as first/last mile or a specific demand segment such as transport for disabled or elderly users, while the latter is typically associated with taxi systems that are intended to serve all mobility in a region in a door-to-door fashion either for single clients or in a ridesharing mode.

Fig. 1 shows a schematic diagram where these two applications are presented, leading to a series of questions that are very important for transport planners and are being addressed through research of different kinds: pilots, transport modeling studies,

Figure 1 Two main usages of vehicle automation in public transport (PT) systems and relevant associated questions.

qualitative studies, and so on. The ultimate set of questions in this figure regards traffic congestion and parking demand, which are two of the most important variables to measure urban mobility performance.

Two main behavior questions are expressed in the figure: what happens to the value of travel time? And what happens to car ownership as a result of both these usages of AVs for PT? These will influence the number of trips done using the several modes of transport available as well as the trip duration in a certain area, which will then affect traffic congestion and parking demand. The real system is clearly more complex than what is expressed in [Fig. 1](#); however, this is simple enough to capture some of the major issues and opportunities of vehicle automation.

The value of travel time measures the trade-off between money and the experience or usefulness of traveling, and it is essentially a perceived indicator as it depends on the people, type of trip, and the mode of transport itself ([Mackie et al., 2001](#)). This is linked to the attractiveness of a mode when it compares to the other competing modes of transport. The general intuition is that a better experience inside AVs will lead to a lower value of travel time, therefore, a higher preference to spend time inside these vehicles compared to current ones. Nevertheless, if this added experience can be realized, it will most likely be on board of private cars, which today have to be driven by the traveler ([de Almeida Correia et al., 2019](#)). In the case of PT systems, the differences are not so obvious.

Private car ownership is linked to the experience in PT AVs, namely the value of travel time savings, but also on what will happen to the private cars themselves. It cannot be assumed that private cars will not evolve as much as PT AV systems. In fact, a great part of the innovation is being driven by carmakers not PT systems per se. These cars will obviously be used in the shared fleets of vehicles mentioned in [Fig. 1](#) as well, therefore benefits can be common to both private and public systems. What will be the most likely usage of these cars is dependent not only on travelers' behavior but also on the policies that will be implemented by public authorities. Currently, cities are already deciding on which vehicles should or should not be allowed to circulate in specific parts of their territories.

Like changes in car ownership, there is also much speculation around the travel times that people will be perceiving as acceptable when riding in an AV, which is again connected to value of travel time savings and also to the vehicle ownership itself. Once more this may make more sense to be discussed with reference to private AVs rather than PT systems where sharing a vehicle is in most cases part of the equation and being a passenger always a reality. It is for private cars that visions of moving living rooms are being put forward. For a SAV, or automated bus/pod, there is the possibility of a redesigned interior since the driver is no longer needed, but it is still difficult to understand how much that interior can be redesigned and customized to the needs of travelers.

The debate over the impacts of AVs in urban transport systems and the overall quality of the urban environments is at its peak. On one hand, AVs could contribute to taking passengers from traditional mass transport systems, such as trains and trams, thus contributing to higher energy spending. [Shaheen and Chan \(2016\)](#) analyzed the impacts of TNCs and concluded that many trips have been diverted from those modes to those new ways of traveling in cities. On the other hand, with AVs there is the possibility of routing these vehicles smartly trying to avoid traffic congestion ([Liang et al., 2018](#)) and parking away from the curb potentially releasing space for other usages. Nevertheless, for SAVs, the requirement for pick-up and drop-off locations is essential. In a recent modeling study by the ITF-OECD authors concluded that "striving to reconcile efficient and safe pick-up and drop-off activities with the productive occupation of space will be a central challenge going forward" ([ITF, 2018](#)). Despite attracting people away from traditional PT, SAVs can yield some benefits: with the use of information technology and the routing flexibility, there is the possibility of maximizing the occupancy of cars and usage of fleets of smaller vehicles 1-seat or 2-seats may be possible as well ([Wadud et al., 2016](#)).

What Do Cities Want From Vehicle Automation?

One of the first relevant pilots with automated shuttles has been the CityMobil and CityMobil2 projects funded by the European Union. The first project ran between 2006 and 2011, including several pilots and modeling studies through which it was concluded that "cybercars" would be better designed "as feeders for PT in areas of low population density" ([van Dijke and van Schijndel, 2012](#)). In CityMobil2 it was concluded that the greatest potential usage for PT AVs would be as "medium-size vehicle as on-demand transport services feeding conventional mass transits in the suburbs of large cities or on radial corridors as complementary mass transits with large busses and platoons of them and as main PT for small cities with personal vehicles" ([Alessandrini et al., 2014](#)).

The industry took the hint and nowadays companies like Navya (2014, France), EasyMile (2014, France), and Local Motors (2007, USA) are providing vehicles for pilot testing all over the world. The ParkShuttle system created by 2getthere (2005, Capelle aan den IJssel, The Netherlands) is the only mature system operational on a daily basis and even without a steward on board ([ATRA, 2020](#)), nevertheless, this is what can be traditionally classified as a personal rapid transit (PRT) system because the vehicles drive on a segregated lane guided by magnets on the road.

There could be several application contexts for on-demand automated bus services since all applications will benefit from savings in personnel costs as referred before, but the one that has been gaining more attention is the first/last-mile connection to higher capacity traditional PT systems such as rail. Recognizing that PT is not able to cover all areas of a city and country and that supplying lower density areas or covering off-peak periods can lead to high costs, automation is naturally being seen as an alternative to cover the connection to and from train or bus stations much like the CityMobil initial project concluded.

In a survey from 2017, Bloomberg asked 38 cities, which were identified as being actively preparing for AVs, what they expected from AV technology and the first and foremost anticipated usage of AVs is what they called the “last mile transit.” Naturally, with the great investment that has been done in the past decades and, in some cases, over the past century on expensive transport infrastructure such as trams and trains for moving masses of travelers, cities are not prioritizing the usage of private AVs in their streets or substituting those networks by AV-based systems. Even if private AVs may increase the efficiency of the usage of each family vehicle by being able to move around driverless to pick-up and drop-off family members (de Almeida Correia and van Arem, 2016). Research has been showing that the first/last-mile trip is many times the most undervalued stage of a multimodal transit trip. But this is a critical stage even for broader goals such as providing equity in job accessibility (Boarnet et al., 2017). Using flexible transport for these connections is not new, already with TNCs today, cities are trying to find ways of harnessing their flexibility and convenience to provide a first and last-mile solution by subsidizing these companies (Shaheen and Chan, 2016).

Potential Impacts on Urban Mobility

Travelers' Behavior

According to Fig. 1, the behavior component of the travelers is essential to ultimately explain what impacts will result in urban mobility systems and therefore the usefulness or nuisance of these systems. In that regard, the question of whether a change in the value of travel time will occur because of these systems when compared to existing ones is very important.

There are still scant studies in measuring the willingness of people to use AVs as PT and these tend to point for somewhat disappointing directions in terms of perceived advantages of such technologies in PT. Yap, de Almeida Correia and van Arem (2016) conducted a seminal stated preference survey in the Netherlands for assessing the AV for last mile of rail trips compared to the existing modes and concluded that the value of travel time increased rather than decreases, therefore, there was no perceived added comfort. There is still great enjoyment among the population in manually driving a vehicle (Kyriakidis et al., 2015); moreover, there may be an issue about safety in using this technology. In a survey from 2017, Deloitte found that quite a number of developed countries had a significant part of their populations feeling they could not trust automated driving. For example, in South Korea this share was 81% and Germany 72%. But it is striking that one year later the same survey had much more optimistic results with a decrease to 54 and 45% for those two countries, respectively (Deloitte, 2018). This goes to show that preferences and perceptions may be changing quite rapidly making it challenging for planners.

Paradoxically when asking people what is the benefit they mostly expect from automated driving people who are willing to use such vehicles tend to point toward safety as the most important one (Shabanpour et al., 2017). There seems to be a tendency for younger well-educated and tech-savvy males to be more willing to try these vehicles, although this is not conclusive (Fu et al., 2019). It is interesting though to notice how most of the time these behavioral studies, especially those that use stated preference techniques, have focused more on the usage of AVs as private transport rather than public vehicles, while for transport modeling studies the focus has been much more on SAVs.

Preferences of travelers will unsurprisingly be connected to what can be done inside an AV and how this compares to currently manually driven cars. One of the few studies that compares current PT vehicles to what the authors called automated driving transport service (ADTS), which is an automatically controlled door-to-door transport service, is the one (Ashkrof et al., 2019) in which it was concluded that “conventional cars and public transportation are perceived as being the least attractive alternatives concerning in-vehicle travel time on short- and long-distance commuting trips, respectively. Preference for ADTS lays between the car and public transportation, neither the best nor the worst alternative in all scenarios.” Showing that it is difficult to clearly mark the advantages of AVs in PT.

The elderly are often pointed as the great beneficiaries of vehicle automation because they would be able to use a car without having to drive one. This can pretty much be said about any group that does not have or does not want to have a driving license. Nevertheless, this is more related to private ownership of an AV rather than PT. Logically if it will be easier and cheaper to implement PT compared to before, this can also benefit people without a driver's license. The elderly (at least the elderly of today) “see benefits in increased mobility and therefore greater independence at a higher age as it allows disabled people to regain lost mobility” (Schmargendorf et al., 2018), and this cannot be ignored.

Transport Modeling Studies

Most transport modeling studies have been focusing on modeling SAV systems because these have a very different way of being operated compared to traditional PT systems. The dynamics of the movements of these vehicles on a network make the supply side of the transport system much more uncertain and highly dependent on the operational strategies that are taken to manage such systems. This had already been concluded regarding one-way carsharing systems whereby trips taken by some clients affect the supply that is going to be offered in the next minutes in a certain area of a city (Jorge and Correia, 2013). The added component of considering sharing the ride among different clients adds more complexity, hence the need to use agent-based disaggregated models where travelers and cars are individually represented (Martinez et al., 2015).

The most well-know studies about modeling the effects of SAVs in a city are probably those of Kara Kockelman (Fagnant and Kockelman, 2018) in Texas and the ITF-OECD model developed by Luis Martinez (Martinez and Viegas, 2017). Typically, these studies aim at estimating the number of required SAVs to satisfy an existent number of trips. Agent-based models explore different AV concepts and conclude that a fleet of shared AVs could reduce the number of vehicles needed to 10% of the current number in order

to deliver the same trips. [Fagnant and Kockelman \(2014\)](#) reach the same conclusion and indicated that it is possible to satisfy the same travel demand with each shared AV replacing around 11 conventional vehicles. However, research also shows that the number of vehicle kilometers traveled (VKT) is likely to increase due to unoccupied trips of SAVs. The increase of VKT could lead to congestion, which might negatively influence the environment because of pollution and the higher required amount of energy. Transport-mode choice is rarely integrated into such methods, which might hide the transfer of passengers from mass PT to car transport as [Shaheen and Chan \(2016\)](#) noted about TNCs.

For the planning of first/last-mile PT, there are several modeling studies that aim at understanding how AVs can play a role in providing access to mass PT. From a behavior point of view [Yap et al. \(2016\)](#) study, that has already been mentioned, showed that people may not find it very different from current options. At least as perceived back in 2016. Nevertheless, it is important to look at the operational side as well since this can determine the potential to use these vehicles as part of broader networks. [Liang et al. \(2016\)](#) studied the usage of shared electric AVs for accessing a railway station by optimally planning their operational area in a profit maximization perspective showing that these systems may be profitable for a certain catchment area. However, EVs are still a limitation due to their charging time. [Scheltes and Correia \(2017\)](#) used the same case study in the Netherlands for a simulation study of the same type of system showing that results on level of service offered to clients is very dependent on the operational strategies such as having or not proactive relocations of the vehicles or how to charge the vehicles if they are electric: one charging station next to the rail station or several ones scattered in the operation area. [Shen et al. \(2018\)](#) studied the integration of SAVs as first/last-mile access to a PT network of high capacity buses and concluded that the SAVs have the potential of improving level of service. [Winter et al. \(2018\)](#) studied the substitution of regular bus services by on-demand automated buses showing that the waiting costs, when added to a generalized cost function of the system performance, can go down considerably because of the expected reduction in waiting time. Nevertheless, most of these studies do not internalize traffic congestion and other more micro aspects such as interaction with other road users. In several cases it is difficult to see what the difference is between AVs and the existing taxi systems or demand-responsive transit systems constituted by human-driven buses besides the lower costs.

Planning for AVs as PT

Cities and regions are driven by goals associated with strategies designed to obtain quantifiable key performance indicators, which are not limited to mobility/accessibility indicators. City planning for AVs is not yet widespread. [Freemark et al. \(2019\)](#) in a recent survey paper found that few local governments in the United States have started to prepare for AVs and have mixed feelings about the effects of AVs. Nevertheless, in the same study, it was found that for those cities that have a plan the most frequent two goals for the implementation of AVs are “increase street safety” and “support transit.” “Improving sustainability” comes right after those two. Municipal authorities seem to find it important to regulate the usage of AVs, especially those who are more skeptical about the impacts of AVs. Nevertheless, the same survey finds that most city plans fail to present any concrete measure or policy for AVs, keeping the speech very general about what may happen with AVs and stating the need to see how this technology evolves. Some cities are suggesting focusing on the testing of technology, which seems to match what is happening in Europe as well where the effort is on piloting. There is a large number of officials who point for concerns with added VKT and urban sprawl associated with lower transit patronage and employment.

Cities will face challenges regarding governance mechanisms and regulations to accommodate a new reality with AVs that has potential impacts on so many subsystems managed by public authorities: movement of people and goods, PT management, traffic congestion, land use, safety, equity, and so on. But still, things are quite undefined from the transport system perspective. Coming back to [Fig. 1](#), it is quite hard still to foresee what usage of AVs will prevail let alone the impacts that can be expected. Specific challenges that cities are facing or will face in the future are summarized in [Table 1](#).

Conclusions

Planning for the usage of AVs as PT is still in its infancy. Despite many pilots where AVs are being tested, most of the work being done is on research aiming at estimating the impacts of different ways of using AVs as part of the transport system. Very few examples can be found of real PT systems integrated with other modes of road transport.

Cities are recognizing the need to plan for the mobility innovations that are being fostered by the TNCs and AV hype. This is reinforced by the fact that some are already facing troubles with TNCs, but regarding AVs, they are not yet developing regulations and specific policies other than promoting experimentation with this technology. This is fair in a sense, given the ill estimation of the impacts of AVs and the difficulty in estimating the probability of every scenario of application of these vehicles together with other system uncertainties in the future.

In this article, we have identified the different ways in which AVs may be used in the PT systems. We have distinguished private AVs, shared AVs, and pod-like systems and have put forward a simple conceptual model of several key behavioral questions associated with these options, namely, regarding the value of travel time and the frequency and length of the trips people will do in the future. It has been found that AVs used as PT may not bring a very different experience, but they do provide an opportunity for lowering the supply costs particularly as first/last mile of existing mass PT.

Table 1 Questions and tentative answers about planning challenges for automated vehicles (AVs) as PT

Challenges	Tentative answers
Regulate how private AVs can access public space? In a reality where private vehicles are being taken out of the cities what should be done with private AVs if they win the battle of the two markets? Amsterdam municipality intends to ban all petrol cars from the city by 2030, for example, (Boffey, 2019).	If private AVs become very attractive, this may lead to higher usage of private cars which ultimately, despite higher household trip satisfaction, may lead to more traffic congestion. Allowing them in certain high demand areas may exacerbate traffic congestion even because people may feel motivated to be comfortably inside one of such vehicles. Exclusion areas have to be defined if demand increases. Though one must not ignore the potential positive effects on traffic safety and efficiency.
Where and how should AVs be allowed to stop for pick-up and drop-off of their clients? Where to locate designated areas for this to happen? Should these movements be forbidden altogether?	Research is showing the challenge that may be posed by the stopping of these vehicles on the road. Some of the currently used parking spaces may have to be converted into stopping areas. Some parts of the road network may be forbidden for these operations. Current TNCs operations serve as a guide for the future.
How to implement AVs into PT systems? Should all possible usages for these vehicles be allowed or should priority be given for a specific usage?	It seems first/last-mile connections should be prioritized particularly in lower density areas of cities that struggle with the provision of good PT. These areas are also usually easier to convert when compared to more dense consolidated areas. Avoiding investing in gimmicks is a concern given the costs of these pilots and a shortage of investment capabilities of most cities.
Should investments be driven by the cities or by private companies? How should public authorities handle their interaction with these private stakeholders?	Current technology is being developed by private companies that want a take on future mobility systems. They are driven by profit. But many PT operators are already private in many cities around the world whereby the service is defined centrally, and concessions are given. The private initiative is not negative per se, but it may need regulation that is already applicable to TNCs, especially in reference to how SAVs will be offered. Competition and access to the market of automated TNCs will also require attention with clear rules on how to operate.
How to tune land use planning and the usage of AVs? Potential for sprawl or leverage for sustainable development?	Private AVs may eventually increase pressure toward farther regions from the city centers where traditional PT performs better. This will have to be controlled. But from a PT perspective, AVs can play an important role in fostering the adoption of transit-oriented development (TOD) policies in which the first/last-mile connections are essential to expanding catchment areas around rail systems, for example. The eventual conversion of parking spaces into quality public space can help move back people who can find themselves reconnected to city centers.

Rationale for Introducing Congestion Charging

Congestion is increasing in many cities around the globe, reducing accessibility and increasing air pollution. One way of addressing the congestion problem is to increase the supply of road capacity by increasing road infrastructure investment or traffic management. Since space is scarce in growing cities, and since new road capacity is expensive, it is usually not possible to reduce congestion only by increasing the supply of road capacity. Hence, to combat congestion, measures impacting demand are usually needed.

If the demand for road space is larger than the supply, it is a scarce resource. As all scarce resources it has a cost: time or money cost. That is, if there is congestion, travelers will pay the cost by queuing. If demand is managed by a congestion charge, the cost of congestion will instead be paid by a charge which means that it is collected and can be re-used. Queuing time cannot however be collected and re-used. Hence, it is more efficient to use congestion charges than queues to allocate scarce road space. When the congestion charges are optimal, we have efficient use of scarce resources. Essentially the most valuable traffic is prioritized, which often has few other options. This is often freight transport, business trips and commuting trips. Of course, parking charges, annual vehicle tax, and fuel tax might also to some extent reduce the demand for car use, and thereby congestion, while generating revenue that can be re-used. However, they are less efficient in reducing congestion since they are not directly targeted toward the bottlenecks causing congestion.

Demand can be managed also by regulations. A possible regulation is to restricting vehicle traffic using a system of odd or even number plates. However, essentially the same problem remains as with queueing: the cost for the drivers not allowed to drive a given day can again not be collected and re-used as a monetary cost and is, therefore, less efficient than congestion charges. Moreover, it is not the most valuable traffic that it prioritized as in the case of congestion charging. Regulations using a system of odd or even number plates can also increase car ownership as an unwanted side effect. For this reason, transport economists have for decades advocated congestion charges to combat congestion (Vickrey, 1963; Small, 1983; Arnott et al., 1994).

However, even if congestion charging is an efficient way of allocating scarce road space, it will not solve the accessibility problem in the cities. Congestion charges will increase the generalized travel costs for most drivers. In other words, it does not solve the problem of high generalized travel costs or accessibility problems. Moreover, congestion charges will often imply that large sums are redistributed compared to net efficiency gains for society. For these reasons, it hands over power over the resources from drivers to decision-makers. The total gain and redistribution effect of congestion charges will be determined by how decision-makers choose to spend or circulate the money.

Urban Congestion Charging Systems Around the World

Already in the 1980s, Hong Kong carried out a trial (1983–85) with electronic congestion charging, but this was abandoned for integrity reasons (Hau, 1990). Since then, many other cities have had plans of introducing congestion charging, e.g. Edinburgh (McQuaid and Grieco, 2005; Rye et al., 2008), New York (Schaller, 2010), and Copenhagen (Rich and Nielsen, 2007). In many cases, these plans have gone quite far with detailed charging designs developed for the city in question, but in the end, the plans have failed in last minute, usually due to low public or political support.

Thus, for a long time, Singapore was the only example of an implemented urban congestion charging system. Singapore introduced a form of congestion charging called the Area Licensing Scheme (ALS) already in 1975 (Phang and Toh, 2004). This was a manual system of tolls around a restricted area. Traffic decreased in the restricted area, but congestion just shifted time and

place. Therefore, the system has been adjusted over the years—the biggest change being from a manual to an electronic road pricing (ERP) system in 1998. This also meant that congestion charging was made more dynamic with charges depending on time-of-day, vehicle size, and route taken.

The second large implementation of an urban congestion charging system occurred in London in 2003 due to major public concern about traffic congestion in the city (Leape, 2006). The London system differs from that in Singapore (and later on Stockholm and Gothenburg) in that it is not based around charging stations, rather it is a daily charge for driving within central London between 7 AM and 6.30 PM on workdays. An advantage of this kind of system is that also driving within the charging zone is charged, but the disadvantage is that it requires a very large number of video cameras which render the system very expensive.

The Stockholm (Eliasson et al., 2009) and Gothenburg (Börjesson and Kristoffersson, 2015) systems followed London and were introduced in 2006 and 2013, respectively. Both are congestion charging cordons around the inner cities. The Stockholm and Gothenburg charges are more similar to Singapore than London, given that they are time-of-day dependent and based on charging stations. A time-based charge called the Controlled Vehicular Access System was implemented in Valletta, Malta, in 2007, replacing a fixed annual charge to enter the city center (Attard and Ison, 2010). The introduction of congestion charging in Valletta benefitted from the successful experiences in London and Stockholm, but also from lessons of the failure to implement congestion charging in Edinburgh (Attard and Enoch, 2011). Furthermore, in Milan, a congestion charging system called Area C is in operation. Area C replaced the previous Ecopass scheme in 2012 and was approved as a permanent scheme in 2013 after an initial trial period (Percoco, 2013).

The Singapore, London, Stockholm, Valetta, Milan, and Gothenburg cases described above are the main implementations of *urban* congestion charging in operation today, which are developed with the objective (at least one of the objectives) to reduce congestion. Therefore, the remainder of this chapter will draw from these examples when describing the effects of urban congestion charging and lessons learnt over the years.

Congestion charging systems also exist in the small towns Durham, UK and Znojmo, Czech Republic, but the literature on these examples is scarce. A number of cities in Norway have toll rings that originally were developed to collect revenues in order to finance transport projects (Larsen and Ostmo, 2001). Since 2017, the Oslo charge is differentiated depending on peak and off peak, light, and heavy vehicles, as well as fuel type (where notably electric vehicles are fully exempt from the charge).

Effects of Congestion Charging

Short-Term Effects

Before congestion charging was introduced in e.g. London, Stockholm, and Gothenburg, many people were sceptical to whether this theoretically appealing policy would work in reality. Maybe road users would not care about a slightly higher cost or maybe they would take a very long time to adjust to the system. However, these apprehensions turned out to be incorrect. In fact, road users adapted very quickly to the new system. For example, in Stockholm, there was a decrease in car trips over the cordon already during the first month of the congestion charging trial of 27% (during charging hours) (Eliasson et al., 2009). The decrease in traffic flow diminished somewhat over time and stabilized at 22% during the trial. Also in London, the flow decrease was high with a reported decrease of 26% for chargeable vehicle movements when comparing spring 2003 to spring 2002 (Transport for London, 2003).

These are large decreases compared to other measures introduced to try to change mode choice of travelers going into city centers, for example, lowering the public transport fares, or improving bicycle lanes. A fairly large decrease in car travel due to cheaper public transport is shown in Cats et al., 2017, who state that completely fare-free public transport in Tallin, Estonia decreased car trips by about 10% in Tallin municipality, but it came along with a decrease of walking trips by 40%. Buehler et al., 2017 argue that it is a mix of policies to encourage walking, bicycling and public transport together with policies that discourage car use (in this case mainly parking charges and limitations on new road construction) that can explain the decrease in car use in central Berlin, Hamburg, Munich, Vienna, and Zurich in the last decades. However, a comparison of the two Scandinavian cities Stockholm and Copenhagen indicates that it can be difficult to reduce car use with more public transport or more cycling (Bastian and Börjesson, 2018). The two cities are similar in size. The share of cycling is 14% in the municipality of Copenhagen, but only 2% in the municipality of Stockholm (LSE Cities, 2013). However, Stockholm has a public transport share of 44% compared to Copenhagen's 34%. So, the share of car trips is virtually the same. The modal shares of Stockholm are very close to those of London. Hence, these numbers suggest that large increases in public transport often reduces cycling and vice versa.

The largest positive surprise regarding the short-term effects of congestion charges was the effect on congestion and car travel times. For example, in Stockholm, congestion did not only reduce close to the congestion charging stations—car travel delay times decreased far out in the network, even for car traffic that did not pass a charging station. The reason for this was network effects—that bottlenecks resolving affected car traffic upstream and car traffic going crosswise. In Stockholm, car travel delay times reduced mostly on arterial roads—by one third in the morning peak and one half in the afternoon peak (Eliasson et al., 2009). The reduction in delay times also leads to more predictable car travel times since the day-to-day uncertainty reduced considerably. The effects on congestion in London were similar to that of Stockholm, with a reported figure from 2003 of 32% reduction in delay per kilometer (Transport for London, 2003).

The case of Gothenburg shows however that smaller reductions in traffic flow, congestion and associated car travel times are to be expected if initial congestion levels are low. In Gothenburg, traffic flow over the cordon decreased by 12% during charging hours

when comparing 2013 with 2012 and travel times only reduced substantially on the innermost arterial roads (Börjesson and Kristoffersson, 2015).

Congestion reduction not only leads to shorter and more reliable travel times, it also leads to improved air quality in the local environment and thereby health benefits. It has been estimated that the Stockholm Trial reduced air-borne pollution by 10%–14% in the inner city (Eliasson, 2014a). It should, however, be noted that it is difficult to measure air quality effects, since it is heavily dependent on weather. Since urban congestion charging works by reducing traffic locally in congested cities, its climate effects are minor. The reduction in carbon dioxide is approximately proportional to the reduction in vehicle kilometers traveled, which in the case of Stockholm was estimated to 2%–3% in the county (City of Stockholm, 2006). Even though improved air-quality was (and still is) one of the main objectives of the congestion charging scheme in Milan, Percoco, 2013 shows that the charge did not manage to reduce pollution, presumably due to motorbikes not being charged.

One notable characteristic of congestion charging is that it is not easy to track what happens to the car trips that adjust to the charge. A substantial share of car trips that are priced off (primarily commute trips) switch to public transport, but far from all. But especially discretionary trips find other ways of adjusting (City of Stockholm, 2006). For instance, the trip can be cancelled, two trips can be combined into one or a trip can be moved to another time-of-day or another day. Since travel behavior varies over time, in the long and short run, it is often difficult for car travelers themselves to recall how and if they adjusted their behavior in response to the charge. Since congestion charging prioritizes the most valuable traffic, it is the trips facing the highest cost of adjusting (having no or few attractive alternatives) that stays on the road.

Furthermore, travel patterns are not as repetitive as transport modelers and perhaps stakeholders tend to think. Data from Stockholm has shown that occasional drivers, passing the cordon three days a week or less, constitute two-thirds of the vehicles passing the cordon (Eliasson, 2014a). Thus, only a small share of car traffic over the cordon is commuting to work on all weekdays. On the one hand, this makes it difficult to follow up and report adjustments to congestion charging. On the other hand, this feature of congestion charging makes it an appealing policy measure since it leaves the decision of which trips to adjust and in what way, to the travelers themselves.

Long-Term Effects

Long-term effects of urban congestion charging are not extensively discussed in the literature but some sources exist (Börjesson et al., 2012; De Lara et al., 2013; Percoco, 2014; Börjesson and Kristoffersson, 2018). However, it is well known that fuel price elasticities tend to increase over time since drivers tend to have more and better options to adapt in the longer time perspective (Goodwin et al., 2004). Increasing price elasticity over time could also be the case for congestion charging: for instance if drivers can find it easier to adapt residential location, workplace location, or family situation over time. One could also argue that the effect would wear off as people get used to the charges, but there is little evidence that this is the case. From current implementation evidence it seems as though there is an initial overreaction to the charges, but that already after a couple of months the effect has stabilized and does not diminish from there on, rather it increases slightly.

The longer a city has had congestion charging implemented, the more difficult it gets to disentangle the effect of congestion charging from other effects such as other travel demand management strategies, city planning and population growth. The baseline from the year before the introduction of congestion charging becomes more and more irrelevant as the years pass by. Some studies have however tried to assess the long-term effects of urban congestion charging a couple of years after introduction. For example, Börjesson et al., 2012 show that traffic reductions from the charges increased somewhat over time when external effects are controlled for.

Over the years, changes are made to the implemented charging systems. For example, in Stockholm, the system was extended to also include the motorway close to the city centers, and peak hour charges were raised both in Stockholm and Gothenburg. Börjesson and Kristoffersson (Börjesson and Kristoffersson, 2018) show that the price elasticities were substantially lower in the case of these system updates compared to the introduction, probably because the most price-sensitive traffic had already adapted when the charges were first introduced. Also, evidence from London (Evans, 2008) indicates small demand effects in response to adjustments in pricing levels.

In Singapore, the charges have been in place for a very long time and are used somewhat differently from other cities. The main objective of Singapore charges is to manage congestion (Goh, 2002). Charges are therefore adjusted twice a year during Summer and Christmas holidays, such that speeds are in the ranges of 20–30 km/h on arterial roads and 45–65 km/h on motorways. This more dynamic way of using the charges as a congestion management tool would be difficult for example in Sweden where a decision by the parliament is needed for every update of the charging scheme.

Designing a Congestion Charging System

The previous section showed that introducing congestion charging can help to reduce congestion in city centers, which is associated with travel time savings, improved local environment and health benefits. Traffic and other effects of congestion charging should however not be taken for granted. Designing a good congestion charging system is a difficult task and it is easy to end up with unintended effects. One likely pitfall is that the charging system results in second-best problems, moving congestion around in time and place. Any route choices available that can be used to avoid paying the charge, will be used. The case of Stockholm is an example

of a simpler situation resulting in few second-best problem, since the city is placed on islands, and it is easy to set charging stations on the bridges surrounding the city center. Another example of a few second-best problems is Valletta, which is situated on a peninsula with a limited number of access roads from the south-west only. A third example is the congestion charge of the New York City approved by the state legislature, designed as a toll ring around Manhattan south of 60th Street. A fourth example is the congestion tolls implemented at the San Francisco–Oakland Bay Bridge in 2010.

Gothenburg and many other cities where bottlenecks are not primarily bridges, on the other hand, posed more challenges to designers in terms of route choices and more charging stations were needed to surround the city center. Also in Gothenburg, the design had to be adjusted over time in order to avoid unintended barrier effects in the north part of the city that caused many citizens to complain about having to pay charges for e.g. driving to their nearest shop.

A sophisticated transport model is important to decide where to place charging stations and which charging levels should be used. The network assignment model will directly show if there are any undesirable route choice effects. Furthermore, reasonable price elasticities in the model will help to decide on the amounts to charge. The most difficult part is typically the dynamic effects of congestion charging. Since traditional transport models are developed to evaluate infrastructure investments, they are often not very good at evaluating time-of-day varying charges and network effects of reduced queuing upstream when bottlenecks are resolved. This is especially important to notice if a cost–benefit analysis (CBA) is carried out, since travel time savings is at the core of the CBA. Travel time savings are often difficult to calculate correctly using a static transport model. Evidence from Sweden show that this is, of course, more important if network effects are large as in Stockholm (Eliasson et al., 2013) compared to when they are small as in Gothenburg (West et al., 2016).

The design of a congestion charging system also includes deciding if there should be any exemptions to the charges. It is important that exemptions are carefully analyzed together with the proposed scheme since they often have large effects on the efficiency and equity of the system. Examples of exemptions include reduction of charge for residents in central London and full exemption from the charge for taxis and alternative fuel vehicles in Stockholm during the first years of operation. In Sweden, the trend has been toward fewer and fewer exemptions. To negotiate exemptions and start and end times of the charges with local stakeholders can be a way of building support for the charges, which the case of Valletta shows (Attard and Ison, 2010).

In theory (see the first section), in an efficient system each vehicle pays for the congestion cost they impose on other vehicles at the specific time and place. Thus, charges should vary not only by time-of-day but also by location and whether one is driving into or out of the city center. However, in practice, an important factor is that the design of the system needs to be easily communicated. In fact, one of the suggested reasons for the “no” in the referendum on congestion charging in Edinburgh was that the system design was not simple enough to be easily communicated to the public (Gaunt et al., 2007). The final design of charging amounts at each time, place and driving direction needs to consider not only efficiency but also equity. Indeed analyzing car use among low income citizens is a very important factor in equity consideration. A look at the greater picture is therefore necessary, including also the use of the system revenues.

Why are Congestion Charges so Rare?

Public Support

One of the main obstacles for introducing congestion charging, even though there is substantial evidence that it works, is often public resistance. Public resistance is not surprising since most travelers and voters will lose from the charges (even if traffic associated with high values of time will gain). The welfare increase for society and individual travelers will depend on how the revenue is recycled, which is often difficult to see for travelers and voters. Hence, if the public does not trust the government to spend the money wisely, this reduces the public support further. Moreover, introducing congestion charges implies that a new tax base is introduced. Once it is introduced, it is easier for decision-makers to increase the charges and extend the system. Again, the public will likely be against congestion charges if they do not trust the government not to increase the charges to become “too high.”

However, public support can be built for congestion charges. Interestingly, both Stockholm and Gothenburg, and several other cities, have reported that the public support increased shortly after the congestion charges were introduced. Other examples include London (Schade and Baum, 2007), Stockholm (Eliasson, 2014b; Eliasson and Jonsson, 2011), Trondheim, Bergen and Oslo (Tretvik, 2003), and United States (Zmud, 2008) quoted in (Anas and Lindsey, 2011). Several explanations for this phenomenon have been hypothesized. Based on an extensive two-wave survey of public attitudes before/after the introduction of congestion charges in Gothenburg, Börjesson et al., 2016 estimated models where respondents’ attitudes to congestion charges are explained by variables such as expected toll payments, value of time, socioeconomic factors, beliefs about effects, and attitudes to related issues such as environment, equity, taxation, government, and pricing policies in general. The authors concluded that status quo bias is the main contributing factor to the increased support in Gothenburg. Contrary to what is often assumed, “larger benefits than expected” does not play any role for the change in support in Gothenburg: the respondents had the same belief in the effect in the before and in the after wave of the survey.

However, the long-term trends in public support in the two Swedish cities indicate that trust in decision-makers might be important to build and keep support for congestion charges over time. Fig. 1 shows how public support for the charges developed in Stockholm. In 2004, over 45% of the citizens of the city of Stockholm stated that they would vote in favor of congestion charges in a referendum. The support fell, however, as the introduction approached and just before the introduction of the charges it had fallen below 40%. Once the charges were introduced, the support increased again and in the referendum in the autumn of 2006, 53% of the

Figure 1 The share of respondents who stated that they would support the congestion charges in a referendum. The question is formulated as: “How would you vote in a referendum about the Stockholm congestion charges?”.

citizens of the city of Stockholm voted to keep the charges (excluding blank votes). Up until 2013, the support for the charges gradually increased to over 70%.

When the charges were increased and extended in 2016 the support for the charges dropped to 60%, which is almost down to the 2006 level. The decline in support could be caused by the extension of the system to an important bypass, the substantial charge increase, or the small effect it had on travel times (the effects are so small that the travelers did not notice them, except for some segments on the bypass). The decline in support could also be an effect of declining trust in the decision-makers: they communicated that the purpose of the congestion charge was to reduce congestion—whereas an important reason is to finance a big infrastructure package.

In Gothenburg, just over 30% supported congestion charges in 2011, and this support declined to 27% just before the charges were introduced (see Fig. 2). Just as in Stockholm, support increased after the introduction, but the referendum in September 2014 still resulted in 55% voting for abolishing the charges (the referendum was only consultative and was not implemented by the decision-makers because the revenue was necessary to fund a large infrastructure investment package (In 2007, Stockholm received a major transport road investment package, 50% funded by the revenues and 50% by the national government and the revenues were earmarked for a new bypass. It led the decision-makers in the Gothenburg region to seek a similar deal, resulting in a broad political coalition in the Gothenburg City Council to support the “West Swedish package”, partly funded by congestion charges (October 28, 2009). The largest investment in this package is the West Link (2.0 billion EUR), which is an 8-km-long rail link including a 6-km-long tunnel under central Gothenburg with BCR 0.45 (Mellin et al., 2011). The co-financing of the West Swedish package is the reason behind the increases in the charging levels in Gothenburg 2015 (it was not justified by congestion). In a poll in the autumn of 2014, just after the referendum, 51% stated that they supported the charges (It is unclear why the support in the referendum in autumn 2014 was lower than in the poll just after. One possibility is that 22% of the respondents in the poll that were undecided had

Figure 2 Share of respondents who state that they are positive or very positive to the congestion charges. The question is formulated as: “How positive or negative are you to congestion charges—part of the financing of the other parts of the package?”

a stronger tendency to vote against. Another possibility is that citizens that are more positive to the charges have a higher response rate in the poll.). After the increases in charging levels, support for the charges fell (as in Stockholm), and since then it has continued to decline.

Political Support

Many cities have failed to introduce congestion charges, for instance Edinburgh, Manchester, Helsinki, and Copenhagen. The lack of congestion charges is often attributed to low public support. However, the Swedish cases and for instance Edinburgh shows that political support might be just as important and that it is primarily determined by the power over the system and the revenues. Political support for the charging scheme was low in the case of Edinburgh and it was decided to hold a referendum about a complicated double-cordon charging scheme even though it was known already before the referendum that there existed a strong public opposition toward a double-cordon (Gaunt et al., 2007).

Before congestion charges were introduced in Stockholm in 2006, all the political parties (except the Green Party) were against them in Stockholm and Gothenburg. This has changed since the introduction of the Stockholm charges, to the extent that all established parties in Stockholm and Gothenburg are now in favor of the charges. The extension of the systems and the increased charging levels are supported by broad agreement in the city councils of both cities. This shift has been driven by the role that the revenues came to play in the negotiations for national grants for transport investments in the two cities. In Gothenburg, this is in spite of the low public support.

Summary and Lessons Learned

The currently operational charging systems in Singapore, London, Stockholm, Valletta, Milan, and Gothenburg show that congestion charges can be an efficient and effective policy measure for combating urban congestion. Moreover, ex-post cost-benefit analyses after the first-year show that congestion charges were socially beneficial in Stockholm as well as in Gothenburg and Milan (Eliasson, 2009; Rotaris et al., 2010; West and Börjesson, 2018). A key concern for policymakers in other cities/countries is obviously to what extent these effects are stable in the long term and whether they are transferable to their cities.

The finding that many of the effects experienced in the cities with operational charging systems are similar, with large differences in terms of city size, public transport use and car dependence, suggests that the positive traffic effects do not hinge upon some particular features of the city. This conclusion is also supported by a model-based study from Stockholm (Börjesson et al., 2014), using the transport model to forecast the effects of the Stockholm charges in scenarios where the road and public transport systems have been substantially modified. Hence, the traffic effects of congestion charges do in general seem to be transferable between cities with different characteristics. Having said that, the case of Gothenburg demonstrates that congestion charges are less efficient if initial congestion levels are low.

Based on the experiences from implemented urban congestion charging systems, the advice to policy-makers in cities planning to introduce congestion charging is to design the system with great care. Designing a system that effectively reduces congestion is more difficult than one could expect. There is a high risk of the second-best problem (i.e. moving congestion around in the network or causing new congestion). The design might, in general, be easier in cities like Stockholm and Valletta (as well as New York for instance) where bottlenecks are located on bridges or a few access roads, and where water is functioning as natural borders, and more difficult in cities like Gothenburg (and for instance Chicago) where the bottlenecks are more difficult to identify and isolate and where there are no natural borders preventing drivers to take undesirable route choices to avoid being charged. To design an efficient system that effectively reduces congestion, important policy advice is therefore to apply a carefully calibrated local transport model in the design process to test many designs and reject the bad ones. In the two Swedish cities, the best-practice transport model could predict the reduction in traffic volumes with high accuracy in the peak.

In several of the cities that have operational congestion charging systems, we have seen that public support increased shortly after the congestion charges were introduced. For this reason, having the referendum after a six-month trial proved to be crucial in Stockholm—had the referendum taken place just before the introduction of the system, a majority would have voted against introducing them (this has also happened for instance in Edinburgh). From a policy perspective, a trial is therefore favorable, and policymakers can study how public support develops before making the system permanent—but the problem is then to justify the investment of large resources in a system that might not survive after the trial. However, for cities like New York, where there are already tolls on the bridges that could be transformed to a congestion charging system, reducing the system investment cost substantially, a trial might be a good idea.

Even if congestion charges are very efficient, they should be used with caution. The net social benefit is often small in relation to the money that is redistributed. A particular problem with the large sums that are redistributed is that congestion charges often is a regressive tax instrument, for example in Gothenburg (West and Börjesson, 2018). This is because the level of car-dependence among low-income citizens is very important for the resulting equity effects. The policy lesson here is that in cities with high car dependence also among low-income groups, the spending of revenue to compensate low-income citizens is critical (for instance, the London system spent a considerable share of the revenues on additional buses in the local public transport service).

A current problem in some of the cities with operational charging systems is that the political focus and justification for congestion charges has increasingly shifted toward the financing of large (prestigious) investments with a low value for money,

that will not benefit low-income groups (or anyone in the coming 10–15 years). This might indeed be one reason why decision-makers in Gothenburg have not been able to build long-term stable public support for the charges there. Hence, in order to build long-term stable support and reduce problems of negative distribution effects, the money should be spent with great care. The Stockholm and Gothenburg cases indicate that the spending of the revenue on mega-investments does not necessarily help build support for congestion charges.

The decline in public support in Stockholm and Gothenburg after system revisions shows that public support cannot be taken for granted even after the introduction of congestion charges. The advice to policymakers is to keep the system as stable as possible over time. If the charges are gradually increased or extended, without large effects on the traffic, there is an increasing risk that drivers will find it more difficult to trust the government not to increase and extend the system only to increase revenue. To avoid such development, it is probably better if any increases in the charging levels are justified by increasing congestion levels, for example, than the need to collect revenue.

Ida Kristoffersson, Senior Research Leader in the field modelling and analysis of passenger transport at VTI Swedish National Road and Transport Research Institute. Her main research area is in development of travel demand models to meet the needs of evaluation of new policies and innovations given the increased attention to sustainability and digitalization of the transport sector. Research interests include transport demand modelling, transport pricing, cost-benefit analysis, and travel behavior.

Maria Börjesson, Professor in Economics at VTI Swedish National Road and Transport Research Institute and permanently affiliated professor at KTH Royal Institute of Technology. External affiliated to the choice modelling center, ITS Leeds. Research interests include transport cost-benefit analysis and appraisal, transport pricing, the impact of the transport system on employment and GDP, choice experiments and econometrics for valuation of non-market goods such as travel time, reliability, and security.

Introduction

Planning for future transport systems has always been—and probably always will be—a complex endeavor. It requires a certain degree of foresight into configurations of technologies, practices, norms and values which may emerge, and require different infrastructures, policies, regulations, and urban forms from those which are in place today. Effective planning and decision-making also requires understanding and appreciation of what does and does not work, and what the main uncertainties are. At the same time, existing physical, social and regulatory infrastructures, educational regimes and so on can lead to the replication of historical “best [planning] practice.” And unforeseen events—such as COVID-19—have the potential to radically shift what previously appeared to be immovable mobility practices (e.g., frequent air travel or car dependency).

The process of transport planning is not passive, but it actively participates in the construction of futures, which may be more or less equitable and sustainable. For example, through their everyday work and micro-decisions, planners and consultants assemble particular futures, which may lock-in or reject the status quo (Lissandrello et al., 2017; Pollock and Williams, 2010). It has, arguably, never been more important to recognize the role that transport planning plays in reinforcing, or rejecting high-carbon, energy-dependent transport practices. As transport has rightly been labeled the “roadblock to climate change mitigation” (Creutzig et al., 2015), questions of energy efficiency, energy inequality, the uptake and use of alternative fuels, and emissions reductions have come to the fore (Oswald et al., 2020). When combined with the inertia in the system infrastructure, vehicle fleet turnover and consumer behavior, the transport systems in developed economies are likely to look very similar in most respects in 2050 as they do today (Anable and Brand, 2019). This chapter focuses on road-based transport, as the major source of transport-related carbon emissions (Sims et al., 2014), and the largest absolute increase in energy consumption in the EU (European Environment Agency, 2019) whilst recognizing the relationships between different spaces: road, rail, water, and air.

Transport and Energy

Processes of movement require some form of energy. Roughly one-third of our energy goes into transportation. Active modes of transport (e.g., walking), which dominated social practice before the emergence and diffusion of the Internal Combustion Engine (ICE) and private motorized mobility, require bodily, “metabolic” energy. To supplement human bodily capabilities, a reliance on animals’ energy systems emerged, by way of horse riding, and horse and carts or coaches—affording a range of new possibilities to those able to use these modes (e.g., carrying heavier loads, traveling further, faster). Scholars from health and physical education have long been interested in the metabolic costs of “moving about” (e.g., Tucker, 1975), pointing to the in/efficiencies of different modes. Such logics of “efficiency” problematically pervade contemporary thinking on transport too, often contributing to a (re) enforcement of prioritizing “the most efficient” mode, which is often understood in terms of reducing bodily efforts, and increasing speed.

The widespread diffusion of ICEs shifted reliance from (animal/human) bodily metabolisms to fossil fuels. Fossil fuels grew in importance as the infrastructures (e.g., petrol stations) became established, know-how and competencies for the ICE grew (e.g., garage repair and maintenance), but perhaps more importantly, the powerful vested interests exerted dominance to prevent alternative fuel types and systems of mobility emerging. Fossil fuels were historically—and arguably remain—relatively abundant and accessible, and provide energy for mobility with high energy density, low weight, and small size of onboard energy storage necessary for mass transportation. Low costs and ease of transportation also contributed to the development of global chains of fossil fuel extraction to consumption. Just 12-30% of the energy from fuels put into conventional vehicles is used to move the vehicle (Department of Energy, ND). This figure depends on characteristics including, for instance, the drive cycle, driving style, and/ or

topography. The remaining 70–88% is lost to inefficiencies in the engine and driveline, and/or used to power in-vehicle accessories. Associated with these chains are well-documented exploitations and violence (Nixon, 2011; this is also the case for some non-fossil fuels, see for example: Branch and Martiniello, 2018). Moreover, and perhaps more often discussed, is the harm associated with the burning of fossil fuels, to both the environment and human health. The burning of fossil fuels is the principle source of carbon emissions (Höök and Tang, 2013). Between 30% and 50% of particulate matter (PM) and nitrogen oxides (NO_x)—the primary air pollutants affecting human health—in cities can be attributed to transport (European Commission, 2019), and diesel fuels in particular (WHO, ND), resulting in increased risk of cardiovascular and respiratory disease and cancer.

In Europe, road transport accounts for the largest proportion of energy consumption in the transport sector (73% in 2017), and in 2017 road transport energy consumption was 34% higher than in 1990 (European Environment Agency, 2019). The transport sector remains heavily reliant on fossil fuels. It is thought that globally, approximately 80% of transport fuels are derived from petroleum, and in the European Union in 2016, 95% of all fuels consumed were oil-derived (all fuels excluding biodiesel, biogas, biogasoline, electrical energy, natural gas, and solid biofuels) (European Environment Agency, 2019). For road transport, alternatives to fossil fuels include biofuels (e.g., bioethanol and biodiesel, either on their own or blended with fossil fuels), synthetic fuels (e.g., Fischer-Tropsch diesel), and electricity. Where the source of the electricity is renewable (e.g., solar, hydro, wind) there are significant benefits for an electro-mobility future, yet alone it is unlikely to achieve emission reductions within the timeframe required to prevent climate breakdown (Anable and Goodwin, 2019). This is because fuel type—and the pollutant content—is just one factor influencing transport energy consumption with other factors including technical efficiencies, modal choice, activity levels, lifestyles, socio-cultural factors, and population composition (Brand et al., 2019). Changing energy vectors and vehicle fleets also takes time; typically less than 10% of the car fleet is replaced each year, which implies a total transformation takes at least 12–15 years (Brand et al., 2020). This highlights the need to be thinking beyond energy supply, to pay closer attention to energy demand. In addition to this, questions have been asked of the sustainable resource use associated with electric battery production (see: Sovacool et al., 2020), with García-Olivares et al. (2018) showing that while a 100% renewable transport system may be feasible, it might not be optimal, as their modeling suggested it might not be compatible with broader sustainability objectives (e.g., decreased resources consumption).

The International Energy Agency (IEA) has noted that the transport sector is at a point of “critical transition,” whereby:

“existing measures to increase efficiency and reduce energy demand must be deepened and extended for compliance with the Sustainable Development Scenario (SDS). This process should be set in motion over the next decade, as any delay would require that stricter measures be taken beyond 2030, which could noticeably raise the cost of reaching climate targets. Combined efforts across all transport modes, accompanied by power sector decarbonisation, will play a crucial role for achieving SDS goals” (IEA, 2019: NP)

The Sustainable Development Scenario (SDS) is framed as an “integrated approach to energy and sustainable development,” outlining pathways to a major transformation of the global energy system, focused particularly on the three Sustainable Development Goals (SDGs) most closely related to energy: universal access to energy (SDG 7), health impacts of air pollution (part of SDG 3), and climate change (SDG 13). The SDS approach signals system-wide change, and points to the need for cooperation across different transport sectors, where, for instance, focusing on a single transport mode may disguise related trends occurring elsewhere in the transport system. An example of this can be seen in the work of Ottelin et al. (2014) who suggest that energy and emissions saved from reductions in car-based transport in urban areas might be replaced by air travel, potentially the result of a rebound effect (i.e., money saved from not owning a car is spent on air travel). Thus the “critical transition” of which the IEA speak acknowledges the need to go “further, faster” (CREDS, 2019), while also accounting for related sustainability objectives, and the connections between the transport system and other socio-economic sectors. Research on Just Transitions has gone some way to highlight the complex intersections of local fossil fuel extraction, economic systems, and decarbonization efforts (e.g., Healy and Barry, 2017), but multiple other connections exist with more or less visibility in academic and/or policy discourse.

Transport Planning and Reducing Transport Energy Demand

As noted earlier, there is a significant challenge to reducing the energy required for the current, and potential future transport demand. Planning and planners have the potential, through their daily practice; to lock in a private-car based transport future through prioritization of a built environment that perpetuates current practices, norms and values (e.g., logics of efficiency and speed, or use of cost-benefit analysis that favors travel time savings). The role of planners in low-carbon transitions has been discussed, with Cass et al. (2018: 166) noting how for planners’ “previous histories, policies, and other co-existing systems and networks affect the processes they hope to influence. Since planners’ actions are defined by these situations, following generic blueprints or transferable recipes for intervention is inherently problematic.” They point to the need for interventions, which pay attention to unique and situation-specific characteristics, which will be defined by historical and existing infrastructures, as well as “other interests and actors, both living and dead” (ibid.).

Thus, transport planning and transport planners have an important role to play in efforts to reduce transport-related emissions and energy demand. In characterizing what this role might be and what solutions will be optimal, research to date has shown that:

- technological efficiency will go some way to reducing emissions and energy consumption, but a wider suite of actions will be required to tackle the unsustainability of the current systems of transportation around the world (Anable and Goodwin, 2019)—thus waiting for technological solutions to mainstream (e.g., technological substitution such as EVs, CAVs) is misguided;
- Solutions need to include both passenger and freight/waste transport, and account for the multiple and complex relationships between transport and a range of social practices and economic systems;
- Solutions also need to account for the important interconnections between transport infrastructures (hard and soft) and practices;
- Close coordination between different sectors, and a range of actor groups is required for the development of a roadmap for decarbonizing and reducing the energy demand of the transport sector.

Scholars have pointed to a variety of ways that transport energy demand reductions, and decarbonization efforts can be accomplished, with important roles for transport and urban planning. This work has broadly agreed that four strategies need to occur to achieve sustainable mobility (e.g., Banister, 2008; Sims et al., 2014). These strategies call for a systemic, socio-technical approach to transport policy and planning. Within each strategy sits a suite of potential behavioral, policy/regulatory and technical responses, and as we go on to show, these solutions are highly connected, where for instance online shopping may reduce the need to travel, but then generates mobility for freight which could then be consolidated increasing the load factor of vehicles, but shifts consumption practices potentially increasing demand. The four strategies are identified as:

1. Reducing the need to travel (i.e., through travel substitution, combining trips, home working)
2. Reducing the distance of required travel (i.e., through land use planning measures, jobs and opportunities closer to home, etc.)
3. Shifting to low-carbon/ low-energy modes (i.e., through high quality infrastructures, promotions, personalized travel planning, etc.)
4. Increasing the efficiency of motorized mobility (i.e., through increased occupancy/load factors, vehicle design, alternative fuels, EVs, lower motorway speed limits, etc.)

People travel for a range of reasons; to get to work or education, for shopping, for leisure activities, to visit friends and relatives, or just for the sake of travel (and resultant emotions—happiness, excitement). Moreover, if we include both the movement of people and of things (i.e., freight, waste), then consideration of a broader suite of consumption practices come to the fore. This travel might be taken by a variety of transport modes; active (e.g., walking, cycling, e-biking, scooting), public (bus, train, coach), private (car, van), or a combination of these. Each mode results in different energy consumption and emissions based on the type of vehicle, occupancy rates, fuel types, distance traveled, and so on. Reducing the need to travel can—it is suggested—completely eliminate a portion of trips, and thus do away with the associated emissions and energy consumption (Brand et al., 2020). To do this requires mechanisms that fulfill the needs previously provided by corporeal mobility.

An obvious example of **travel substitution** is online shopping, where home delivery replaces the need for individual customers to travel to shops. From a passenger perspective, travel decreases, yet from the freight perspective it increases—pointing to the relational mobilities between passenger and freight. Consolidation of deliveries (ensuring a full delivery van) offers the greatest sustainability potential (Jaller and Pahwa, 2020)—and increases the “efficiency” of the transport, yet high rates of product returns and non-delivery (i.e., when the purchaser is not home to receive the parcel) contribute to an increased number of trips associated with purchases. Moreover, online shopping increases exposure to “consumerism and materialistic messages” (Guillen-Royo, 2019), with the potential to accelerate purchasing behaviors and shift social practices. For the freight sector, practices of dematerialization (e.g., e-readers replacing books and Spotify replacing CDs) have the potential to reduce the physical movement of material items, replacing it with digital transactions. Similarly, the emergence of 3D printing has the potential to reconfigure logistical networks. 3D printing could radically alter the construction sector, for instance, with the need for complex logistical patterns of mobility reduced, along with volumes of waste. Instead, materials would be “printed” on-site presenting an opportunity to rethink production, distribution, and consumption practices (Birtchnell and Urry, 2016), and potentially disrupting current transport systems and associated energy systems.

Digital technologies have a variety of potential further application, which may **reduce the need for mobility**. So-called “virtual mobilities” operate to digitize communication using information and communication technologies, including social media (e.g., Twitter, Facebook, TikTok), and communication apps (e.g., WhatsApp, WeChat, Telegram). It has been claimed that these technologies allow for communication, which may reduce the (perceived) need for physical co-presence. Yet research has shown that ICT is used for different types of communications than those, which take place face-to-face (Hopkins et al., 2019). Thus, assuming that technologies alone will facilitate substitution behaviors may be misguided. Instead, it is likely that conditions which allow for reduced travel need to be constructed—this might include flexible working policies, which enable some people to work from home thus reducing commuting mileage. It is important to note, however, that reduced daily mobility may be replaced by increased long-distance travel, resulting from rebound effects (Ottelin et al., 2014) or geographically stretched social networks (Urry, 2003). It is also important to acknowledge that digital technologies have often large energy demands and associated emissions (e.g., through data centers), and these need to be taken into account when digital platforms are used as substitutes to physical mobility.

In efforts to **reduce the distance of travel**, better linkages between transport planning and urban planning is required. This may contribute to more compact cities; a move which has the potential to both reduce the need for (motorized) travel, as well as the distance of travel—thus increasing the likelihood of shifting to low-carbon/low-energy transport modes. The per capita energy

consumption for transport in Houston, TX (urban sprawl) is a factor of about 10 higher than in a compact, multimodal city such as Copenhagen. It is important to highlight the difference here between calls for compact versus dense cities. A compact city is not necessarily dense, but offers relatively close proximity to the services that one might require in everyday life—shops, doctors, schools, and so on. Proximity is not the only measure of accessibility, but a sensitively designed compact environment may present some opportunities to reduce the need for or distance of travel for some members of the population. Moreover, cities are already responding to challenges including urban air pollution by way of developing schemes, which restrict—or ban—particular types of vehicles within particular portions of the city. These low-emission zones and congestion charges can provide a lever to promote alternatives to the private vehicle, particularly where investment in public transport provision and infrastructure for active modes occurs in tandem. Thus, urban planning, and the design of more compact environments may help to create the conditions in which increased public transport, walking and cycling can be adopted (Hickman et al., 2013), thereby decreasing energy consumption and harmful emissions.

Infrastructures—many of which are both carbon inducing (e.g., new roading projects) and hold embedded carbon—have the potential to lock-in high-carbon practices for future generations. Yet this does not need to be the case. There are examples where infrastructural lock-in has been overcome. For instance, where urban roading is re-purposed into urban parkways, where lanes of traffic are redesigned into separated cycleways. Creative use of existing infrastructure—even temporarily—can disrupt the dominance of high-carbon mobility in important ways. A prime example is the so-called Barcelona “superblocks” model (similar to Seattle’s “Home Zones”). Superblocks are “repurposed” neighborhoods of nine blocks where traffic is restricted to major roads around the outside, opening up entire groups of streets to residents, pedestrians and cyclists. It has been shown that Barcelona could save hundreds of lives and cut air pollution by a quarter if it fully implements its radical superblocks scheme to reduce traffic (Mueller et al., 2020). These examples are important because they show that change can—and does—happen. This is not intended to encourage the development of further roading infrastructure at the expense of investment in public and active modes, but just to show that the cycle can be reversed, infrastructural lock-in need not be viewed as a fixed barrier to decarbonizing transport or as justification for fatalism (“what can we do, we’re tied into car-based transport?”). There are examples of cities where decision makers and planners have achieved a transition from car dependence to pedestrian/cycling friendly urban form without radical changes to the built environment in the short term.

Current uncertainties of future transport systems are compounded by a variety of socio-technical innovations which are unsettling the existing regime, but the long-term implications of which are still broadly unknown. For instance, connected and autonomous vehicles (CAVs) are promised to respond to a variety of issues of the current transport system, including pollution and inequality; the growth in electric two-wheelers including e-bikes, e-cargo bikes, and e-scooters may extend active modes to a wider proportion of the population; mobility-as-a-service has the potential to reshape ownership models and increase sharing practices. Yet all of these (and other) innovations—which have the potential to reduce energy demand—are contentious and impacts are uncertain, with potential rebound effects (Sorrell et al., 2020), which may increase rather than decrease overall energy demand.

Beyond the “Minority World”

Without intending to repeat well-trodden discussions of the importance of acknowledging the heterogeneity of countries and cities around the world, it is also important to note the limitations to existing work on transport and energy, with much of the discourse and academic scholarship centered on a limited set of geographical regions for case studies and theorization.^a There are—of course—exceptions to this, with rising attention paid to China’s transport system and responses to issues associated with increased car ownership (Zhang et al., 2017; Yang et al., 2017). To here in this chapter, much (although not all) of the examples and case studies provided relate to the United Kingdom and northern Europe, where the authors are based. The narrative outside of Euro-America can work to homogenize transport systems and mobility practices, and understand these largely in relation to automobility (a private car dominant system of mobility). There are important reasons to ensure thinking on transport energy demand is not restricted to scholars and case studies of the Global North (also known as “Minority World” to reflect the relative current and future population sizes, relative to the “Majority World”). The dominance of Euro-American theorization and case studies across transport has been reported (e.g., Schwanen, 2018). A growing issue for transport planning is thinking through the implications of energy demand reductions in and for contexts beyond the existing cases.

Alternative issues arise in different geographies, for instance, Adom et al. (2018) point to the issue of constrained energy supply, demographic trends, economic growth, poor and unsafe infrastructures, and rapid urbanization in some African countries, as particular challenges for planning transport systems. The relationship between transport and economic growth is a complex one, which is characterized by a politics of developmentalism. Wang et al. (2019), for instance, show how urbanization, road infrastructure, economic growth, and industrialization are stimulating road transport energy consumption in Pakistan. In their analysis of MENA (Middle East and North Africa) countries, Saidi et al. (2018) found that energy consumption for transport works to stimulate economic activities and economic growth, but reflect on the need to account for the negative externalities of increased motorized mobility, pointing to the need for thoughtful infrastructure development, regulation and policy to prevent unrestrained increases in the physical infrastructures (with their own embedded energy and carbon) and associated automobility. In their

^a While Euro-America has dominated transport scholarship, other locales also have traction for specific reasons, for instance, South-East Asia for its application of ICT to leapfrog some dimensions of private car dependence, and South America for Bus Rapid Transit (BRT) systems.

investigation of West African countries, Adom et al. (2018: 919) found that rebound effects limited the energy conservation potential of pricing mechanisms, and concluded that “in the long-run, price disincentive tools have to be higher than a required price threshold in order to induce energy conservation behaviours in these economies.”

With all of this, there are important questions to ask of the multiple ways that colonial and postcolonial transport and urban planning have—and continue to—“shape the urban built environment, planning laws and institutional processes” (de Satgé and Watson, 2018: 31). There is, therefore, much work to do to offer more nuanced and sensitive assessments of transport energy demand and transport planning beyond Euro-America, and to understand this in connection to a broader suite of concerns. This may include seeking to integrate sustainable development scenarios to examine the complex intersections between energy and sustainable development as it plays out in a variety of contexts, cultures, urban forms and regulatory arrangements.

Conclusions

Mobility has long been viewed as integral and highly beneficial to social and economic life. Yet, as we write this (March 2020), novel Coronavirus COVID-19, still in its infancy, has already radically changed perspectives on the types of mobility that are perceived to be “necessary” and/or “essential.” The very concept of “necessary transport” has, for some, been upended. Suddenly, the previously immovable work trip is being conducted virtually. Some trips to visit family and friends have become “non-essential”. These events, which are hard to predict and plan for, offer the potential to reconfigure the importance placed on corporeal mobility, with early suggestions that COVID-19 could have substantial and significant implications for global aviation, but it is also likely that it will have an effect on more localized travel, including most forms of sustainable public transport and shared mobility. Working from home, where possible, is already one of the UK government’s recommendations while COVID-19 is in “containment” stage. Home delivery of supermarket goods and take away food are being recommended for those with symptoms—shifting the energy consumption from passenger to freight vehicles. Another potential implication could involve increased travel by private car, as people seek to avoid contact with others and thereby avoid shared (public) transport modes.

There are a host of issues associated with the dominant transport system, which is dependent on private mobility and fossil fuels. The technological shift to electrification is likely to be one part of the answer to the “net zero” clean energy challenge, but it is by no means the whole answer. To radically, systemically and quickly reduce the energy intensity and carbon dependency of the transport system will require major shifts in mindsets, ideas, norms, and practices as well as infrastructures, policies and regulations. Reducing energy demand therefore requires the support and coordination of multiple actor groups—including transport and urban planners. It requires out-of-the-box thinking, which challenges the status quo, and looks to alternative ways to configure transport systems which accounts for energy, but also pays attention to interconnected issues of access, equity, and affordability for diverse populations and geographies.

Introduction

Transport systems have significant environmental, social, and economic externalities associated with them. These systems provide mobility and physical access to resources, goods, markets, and other amenities enhancing the quality of life. Therefore, several externalities positively affect people's lifestyles, in terms of economic growth, educational opportunities, land value, and so on. On the other hand, there are several negative externalities, such as air and noise pollution, energy consumption, traffic congestion, cost of living, and traffic crashes, with direct negative consequences on public health and welfare (World Bank, 1996; OECD, 1999). The increase of negative externalities has been expedited by the continuing modal shift in favour of the private car, which is the most detrimental form of motorized transport. Modal substitution would represent an important strategy of demand management for the achievement of a sustainable transport system, by providing, as an example, better modal alternatives like PT systems characterized by high-quality levels. Improving PT SQ is important in order to keep the current users and to attract new ones. With the aim to guarantee better PT services, all the actors involved in the PT business should assure well-organized PT systems and allow people's need for mobility to be satisfied under safe and comfortable conditions. PT agencies must provide methods for measuring and monitoring their performances.

There is a variety of aspects that characterizes a PT service. According to the Transit Capacity and Quality of Service Manual (TRB, 2003), SQ factors can be distinguished into two main broad categories: availability factors, and comfort and convenience factors. The availability factors include service coverage, scheduling, capacity, and information; on the other hand, the comfort and convenience factors include passenger loads, reliability, travel time, safety and security, cost, appearance, and comfort. An alternative classification of PT SQ factors can be found in the European Standard (EN 13816) by the European Committee for Standardization (CEN, 2002), which classifies the SQ factors into the main following categories: availability, accessibility, information, time, customer care, comfort, security, environmental impact. Aside from the various classifications, PT SQ depends on many different aspects, and just for this reason it is important to investigate these in order to identify which are the most important or the most critical for the users, with the final aim to satisfy customers and attract new ones.

For a long time the performance evaluation of PT has been carried out from the service managers' perspective. However, in the last few decades, SQ has become a major area of attention for practitioners, managers, and researchers, who have focused on the passengers' perspective.

This chapter wants to provide a picture of the state of the art concerning the SQ analysis in PT sector, with a particular attention to the perceptions of the passengers about the used services, in terms of satisfaction with the services. In the rest of the paper, we will clarify the relationship between SQ and customer satisfaction, and other fundamental concepts; then, we will give an overview of the methods adopted and proposed for measuring and analyzing SQ in PT, and finally we will provide new challenges of studying and analyzing SQ.

The Concepts of Service Quality and Customer Satisfaction: A Historical Perspective

SQ can refer to four points of view: the customer, the service provider, the service beneficiaries (customers and community), and the service partners' (operators, authorities, etc.). Starting from this assumption, some concepts linked to SQ can be better understood. The EN 13816 (CEN, 2002) defines four main concepts of SQ. More specifically, there is a level of quality, named as "quality sought," which is required by the customer, and a level of quality, named as "quality targeted," which the service provider aims to provide for the customers; this level is influenced by the level of quality sought. On the other hand, "quality delivered" is defined as the level of quality achieved on a day-to-day basis. Finally, there is the level of quality perceived by the customer, which is named as

“quality perceived.” In particular, the difference between “quality sought” and “quality perceived” may be taken as the degree of customer satisfaction. This definition has been largely supported in the literature; several researchers, in fact, view SQ as a means of achieving user satisfaction (Chen, 2008). Also according to the Transit Capacity and Quality of Service Manual (TRB, 2003), the concepts of SQ and customer satisfaction are interconnected. The manual defines SQ as the overall measured or perceived performance of PT service from the passenger’s point of view. Many researchers consider the customer’s point of view as the most relevant for evaluating PT performance.

Customer satisfaction in PT has been studied since the mid-1960s (TRB, 1999), and since the 1990s, the application of marketing techniques has provided transport researchers with a tool to study satisfaction with respect to travel (Fornell et al., 1996). The concept of satisfaction with travel has therefore been well established over time, and frequently discussed and used in the literature. The concept of SQ linked to the concept of customer satisfaction dates back to the 1990s, when Berry et al. (1990) pointed out that “customers are the sole judge of SQ.” Parasuraman et al. (1985) state that the perception of SQ is the result of a comparison of consumer expectations (i.e., quality sought) with actual service performance perceptions (i.e., quality perceived). Other authors, however, do not take expectations into consideration (Cronin and Taylor, 1992). While perceptions are usually measured by satisfaction ratings, there are varying interpretations of expectations. Teas (1993) stated that expectations could be interpreted as predictions of service, as an ideal standard, or as attribute importance. Smith (1995) contends that a number of researchers have directly substituted importance measures for expectations, affirming that measuring service attributes that are important to customers may be more meaningful to managers than measuring customer service expectations.

The relationship between SQ and satisfaction is not clear. In the literature, SQ usually accompanies satisfaction. This may be due to the similar nature of the two concepts, which both derive from the disconfirmation theory (Parasuraman et al., 1988). Some authors think that customer satisfaction causes perceived quality and others consider that SQ is a vehicle for satisfaction (e.g., Chen, 2008). More recently, since the beginning of the twenty-first century, a number of studies have focused on aiming to understand what drives satisfaction compared to loyalty, and it has become important to understand the differences between these two commonly used terms. In the PT context, loyalty is defined as a customer’s intention to use the service in the future based on previous experiences (TRB, 1999). Although it is possible to measure satisfaction without considering loyalty, the results of recent studies suggest that the reverse would be theoretically illogical as satisfaction tends to influence loyalty (van Lierop et al., 2018).

The Measurement of Service Quality in Public Transport

As largely discussed in the previous section, a widely adopted SQ measurement in PT is based on the customer point of view, even if SQ in PT is generally measured also from the service provider point of view by a range of disaggregate performance measures, which provide an “objective” evaluation of SQ. These measures can be derived from different sources of data; as an example, they can be calculated from information an agency would normally have in hand for other purposes (e.g., schedule data, system maps, complaint records, and so on). A particular form of manual data collection can be represented by the Passenger Environment Surveys (PES), which generally assess qualitative elements which are difficult to measure by any other way. In fact, PES use a “secret shopper” technique, according to which mystery riders travel through the PT system and rate a variety of trip attributes in order to provide a quantitative evaluation of factors that passengers would think of qualitatively (TRB, 2003).

On the other hand, the measurement of SQ from the customer point of view can be considered a subjective measure of SQ. It is generally derived from the well-known Customer Satisfaction Surveys (CSS); CSS are useful to help prioritize SQ improvement initiatives, measure the degree of success of past initiatives, and track changes in SQ over time (TRB, 2003). According to the CSS, users express their judgments about the services according to a predefined scale of measure. The kinds of scale of measurement most frequently used are the Likert, verbal and the numerical scale (Hill, 2003). User perceptions can be expressed also in terms of choice, which are collected from experiments based on Stated Preferences (SP) techniques (Hensher and Prioni, 2002). In this case, users are asked to make their choice among hypothetical services characterized by service aspects having certain levels of quality; by making the choice, the user gives indirectly a relevance to certain aspects rather than another aspects. An alternative kind of data is represented by the best-worst scaling, according to which users have to indicate which is the best factor and the worst one in terms of satisfaction and importance (Echaniz et al., 2019).

Analyzing Public Transport Service Quality in Terms of Passengers’ Perceptions: Theoretical Approaches

The analysis of SQ based on passengers’ perceptions has been extensively studied in the transport literature. There are many authors who worked on this issue and who continue to investigate and propose methods for analysing SQ in PT starting from data collected through surveys addressed to passengers. The literature is rich of studies analyzing different PT modes, from services offered by PT systems such as buses to railways services, or airport and airline services. Independently of the analyzed transport modes, the various studies differ in terms of approaches adopted for investigating SQ. The adoption or the development of the different methods has to be chosen as a function of the objective of the analysis. There are simple or more advanced methods and techniques depending on the level of detail that the analyst wants to achieve. The literature provides some techniques developed in the marketing field aimed to measure SQ in terms of customer satisfaction; the most famous being SERVQUAL (Parasuraman et al., 1985), which is an index function of the differences between expectation and perceptions of the users about a series of SQ factors. This method has been

largely applied in the literature, and several authors proposed also some modifications. This kind of method provides a measure of the level of quality of the service, based on the perceptions of the users about the single SQ aspects. There are similar methods such as the Customer Satisfaction Index (CSI) (Hill et al., 2003), which represents a measure of SQ on the basis of attributes' importance and satisfaction rates. Also for this method the literature provides several applications and modifications (e.g., the HSCI proposed by Eboli and Mazzulla, 2009). Next to these techniques providing an overall SQ measure, there are some practical techniques that provide only a measure of the level of quality of the single SQ factors. An example of these techniques is the Importance-Performance Analysis (IPA), which is a quadrant analysis that uses importance and performance as coordinates (Martilla and James, 1977). In general, the methods that adopt the importance concept can have two variants: the importance can be the importance directly stated by the passengers during the interview, or it can be calculated starting from the satisfaction rates, through correlations or regression weights of the satisfaction rates expressed for each SQ factor and the satisfaction expressed for the overall service.

Other interesting methods aiming to provide a level of SQ for each service factor is represented by procedures based on the combination of subjective and objective indicators calculated on the basis of users' perception about the service and measurements provided by the PT agency (e.g., Eboli and Mazzulla, 2011). The aim of the above mentioned methodologies is to obtain a measure of the overall SQ or of the quality of the single service factors, with the final goal to improve the level of SQ as a function of the criticalities registered through the application of the measurement method. On the other hand, there is a wide series of methodologies that allow the relevance of each service factor to be derived, with the final aim to understand which are the service aspects to which the service provider must point for improving the service and satisfying the users. There are simple techniques such as factor analysis, regression models, and more advanced methodologies such as Structural Equation Modeling (SEM), which allows the modeling of a phenomenon by considering both the unobserved "latent" constructs and the observed indicators that describe the phenomenon (de Oña et al., 2013). These models are generally applied by using satisfaction rates expressed according to different kinds of scale. An extension of these models can be found in the studies that introduce also the loyalty next to the more traditional concepts of SQ and customer satisfaction (e.g., de Oña et al., 2016a; Chen, 2016). Another method allowing the characteristics that most influence overall SQ to be identified is the classification and regression tree (CART) approach. The CART methodology can provide more useful and informative results than other approaches because of the "If-then" rules generated from the trees (de Oña et al., 2015).

There are other kinds of models that adopt data collected from experiments based on Stated Preferences (SP) techniques. These types of data are usefully analyzed through discrete choice models based on the Random Utility Theory (RUT), according to which users are rational decision-makers who make their choice by maximizing their utility. Although over the last few decades discrete choice models have been widely used for simulating the choice among different transport modes, within mode models have been proposed where the alternatives relate to a single transport mode, usually PT. Hensher and Prioni (2002) first proposed a methodology for measuring SQ in PT through the choice-based conjoint analysis. The work of Hensher have been followed by other authors who proposed more advanced models aimed to investigate on the relevance of the various SQ factors starting from the choices made by the users between the habitual service and more hypothetical services; by choosing his/her more attractive service the user indirectly expresses a judgement of importance about the service aspects. Examples of these models can be found in dell'Olio et al. (2011) and Eboli and Mazzulla (2008, 2010).

New Challenges

This section presents a picture of the most recent studies and the new trends in the analysis of SQ in PT. Some of these new methods represent advances of more traditional methods. In fact, some authors recently proposed more advanced SEM for better investigating the heterogeneity in passengers' satisfaction; as an example, Structural Equation Multiple Cause Multiple Indicator (SEM-MIMIC) models were proposed by Allen et al. (2020) and SEM Multi-Group Analysis (SEM-MGA) by Allen et al. (2019). Investigating the heterogeneity among users' is important in order to search for differences among users' perceptions, findings that can be useful for PT operators for identifying the most appropriate strategies for satisfying the various categories of users. Other authors pointed on an extension of the methods based on the use of SP data, and specifically for investigating not only on the opinions of PT current users, but also of the potential users, by introducing the concept of desired quality next to the concepts of expected and perceived quality (dell'Olio et al., 2011; Bellizzi et al., 2020). In this way, PT planners and operators could conveniently consider the opinions of potential users, and not only users, in order to satisfy the expectations of the users, but above all to accommodate the desired levels of quality of the potential users.

Another interesting challenge is represented by SQ analysis over space and time. Although SQ in PT has been widely investigated, only few studies considered the variability of passengers' opinions in terms of space and time, given that the major part of previous studies analysed passengers' satisfaction with PT services in a cross sectional manner only. However, it is common knowledge that passenger's perceptions about PT SQ attributes strongly depend on the context to which the passenger refers. For this reason, each attribute judged by users in terms of satisfaction or importance could show spatial and/or temporal variability. Recent examples of this kind of studies can be found in de Oña et al. (2016b), who proposed the use of the index numbers usually applied in the economic and industrial field for analyzing the variation of SQ over time, and Eboli et al. (2018) who investigated SQ at railway stations aiming to suggest a methodology for analyzing spatial variation of SQ attributes.

Conclusion

This chapter aimed to provide an exhaustive picture of the research and the methodologies proposed in the literature for assessing PT SQ. The work could represent a useful instrument for the researchers of the sector and practitioners interested in the measure of SQ based on passengers' perceptions. The chapter attempted to give also an idea of the future concerning the investigation on PT SQ.

Introduction

The paradigm of sustainable mobility is currently very high on the agenda of policymakers because transport is widely believed to generate many externalities in terms of pollution, congestion, and accidents (Banister, 2008). Transport accounts for about 23% of energy-related carbon dioxide (CO₂) emissions and 15% of global greenhouse gas (GHG) emissions. According to the European Union, cars are responsible for approximately 12% of total EU CO₂ emissions (Bergantino et al., 2019). To tackle this issue, an increasing number of cities are adopting a wide variety of policies aimed at promoting the shift from private fuel-consuming cars to more sustainable transport means, such as public transport, bikes, and ecological vehicles.

This gradual shift has been enhanced by the introduction of tolls on roads (Percoco, 2013, 2014; 2016), incentives for green cars (Coat et al., 2009) and the expansion of public services (Shaheen and Cohen, 2013). More recently, sharing mobility has attracted the interest of policymakers because of its potential impact on car ownership and ultimately the number of kilometers travelled in urban areas. The potential of car sharing in reducing car registration is a topic of considerable attention in the automobile industry. Each shared car can be used by more than one person, and for this reason, the car sharing fleet is expected to substitute more private cars than the number of shared cars, thus reducing the total number of cars (Liao et al., 2020). The literature on the topic is very limited, although growing, especially from the empirical perspective. Nevertheless, in this article, we review existing studies and provide new evidence from Italian cities.

The European Commission's White Paper of 2011, namely "Roadmap to a Single European Transport Area—Towards a competitive and resource-efficient transport system (28/03/2011)" imposed a reduction of 60% of GHGs (compared to 1990 levels) in the transport industry by 2050 upon all European Union member states. The Italian government has attempted to intervene in private car utilization for 10 years by attempting to introduce and regulate alternative methods of mobility and pursuing a circulating fleet renewal. As a result, Italy saw the inception of the "Iniziativa Car Sharing" program (ICS), a voluntary agreement between some Italian municipalities that provided the first car-sharing services with a common organizational set-up. The free-floating approach immediately gained consumer confidence, and the number of registered users increased dramatically in a short period of time. For instance, the number of daily car-sharing rides in the city of Milan increased from 29 at launch to 5000 after four months and up to 10,000 after one year. In 2017, the registered users numbered 1.3 million people, 820,000 of whom were active users (Ciuffini et al., 2017). Milan has been the forerunner of the sustainable mobility paradigm, but several other major cities followed: Rome, Turin, Florence, Catania, and Bologna (Rotaris and Danielis, 2018). In this article, we review the literature on the impact of car-sharing and discuss some empirical evidence on new car sales in Italy.

A Review of the Literature

The impact of car-sharing on car ownership has been studied in a limited number of papers. Myers and Cairns (2009) conducted a survey of users of four UK car-sharing operators and found that the effect of sharing mobility on car ownership may take different forms: (1) the decision of users to sell their cars, resulting in a reduction in car ownership; (2) vehicles being scrapped, resulting in a decrease in the circulating fleet of cars, and (3) the decision to avoid a new car purchase, resulting in a reduction of the number of second cars owned by households. Myers and Cairns (2009) found an overall reduction in vehicles after the introduction of car-sharing because some users decided to sell their cars, not to buy a new car or to get their cars scrapped after they signed up with a sharing mobility service. Similar results were also obtained in Bremen (2005) for both private and corporate users by Maertins (2006) and Knie and Canzler (2005) in Germany and by Ueli et al. (2006) in Switzerland. The reduction in the number of vehicles is also supported by Martin et al. (2010) in various cities, Cervero and Tsai (2004) in San Francisco Bay Area, Price et al. (2006) in Washington DC, Zipcar (2005) in various cities, Lane (2005) in Philadelphia, Ryden and Morin (2005) in Belgium and Bremen city, Carplus (2014) in London and Ademe (2013) in Paris. A recent study of Liao et al. (2020), considering the Dutch population, show

that around 40% of car drivers are able to replace some of their private car trips by car sharing, and 20% indicated that they may forego a planned purchase or shed a current car if car sharing becomes available near to them.

A reduction in fuel consumption due to car-shared fleet efficiency as compared to the average of a circulating car fleet was detected by the *Mobility Genossenschaft* (2009) in Switzerland; by *Knie and Canzler* (2005) in Germany; by *Carplus* (2007) in the UK and, finally, by Information By E-mail Taxystop in Belgium. In their analysis, *Martin and Shaheen* (2011) transformed the fuel consumption savings into emissions reductions (measured in terms of avoided tons of GHG). The finding was an overall reduction of 34% of GHG emissions due to the efficiency of the new cars introduced by the car-sharing providers in North America. This methodology was also used by *Carplus* (2014), which updated his previous study and focused on the city of London, excluding other UK cities. The result was an estimated reduction of 410 kg of CO₂ per year in the UK's capital city. A decrease in the overall distance covered by private vehicles after the car-sharing was introduced (measured in vehicles per km) was found by *Martin and Shaheen* (2011) in North America; by *Cervero* (2003, *Cervero* (2003, 2004, 2008) and *Cervero and Tsai* (2004) in the Bay Area of San Francisco; by *Ryden and Morin* (2005) in Belgium and the German city of Bremen; by *Carplus* (2014) in London, by ICS (2009) in 10 Italian cities; by *Sioui et al.* (2013) in Montreal and by *Ademe* (2014) in Paris.

All these studies involved a station-based car-sharing service and showed that the users, at various magnitude, did reduce their habits in terms of distance covered after car-sharing was introduced in comparison to previous travel behaviors. For instance, the average daily reduction in terms of vehicles per km was 2% for the San Francisco Bay Area (*Cervero and Tsai*, 2004), and 45% in terms of vehicles per km in the German city of Bremen (*Ryden and Morin*, 2005).

In Montreal, *Sioui et al.* (2013) compared two analyses carried out simultaneously. The first studied a sample of 14,500 users of the *Communauto* car-sharing provider, while the second took into consideration the transportation routines of Montreal citizens, whose data were collected by the statistical offices of the city. The authors divided the sample according to the number of private cars owned by the households. Interestingly, people who owned one or more cars and were also car-sharing users drove much less than those who did not subscribe to a car-sharing service. In particular, in a household with one car, a car-sharing customer drove 28% less as compared to someone who was not a user. With two cars available in a household, the reduction reached 57%.

The aforementioned literature considered station-based car-sharing services, whereas comparatively little attention was devoted to free-floating services, which promise to be more flexible and pervasive. A notable exception is the work of *Martin and Shaheen* (2016), who studied a significant sample of *Car2go* users in five major North American cities, San Diego, Seattle, Vancouver, Calgary, and Washington DC, from 2014 to 2015, finding a reduction of up to 10% for newly registered cars. *Martin et al.* (2016) also found that the presence of car-sharing also reduced private car utilization (detected through the decrease in distance covered), but the magnitude of the reduction may not be precisely determinable. Specifically, GHG emissions were reduced by around 39,127 tons in a year (upper estimate) due to *Car2go* presence: -8137 tons in Calgary, -5371 tons in San Diego, -9080 tons in Seattle, -10,027 tons in Vancouver, and -6512 tons in Washington DC. The "modal shift" toward more environment-friendly forms of transportation implied that the car-sharing users in those cities did not change their habits regarding the use of bikes and trains. They traveled more by foot (+ 11%), and, finally, they reduced their frequency of use for both public means of transport (12% for the underground and 25% for public buses) and taxis (55%).

The negative effect of car-sharing on new car sales was detected by *Schmidt* (2020) in some German cities, where free-floating car-sharing had been present for longer.

Some Empirical Evidence From Italy

In this section, the empirical analyses used to determine the impacts of free-floating car-sharing's introduction are identified. Starting from a panel data layout, we estimated several versions of the following Eq. (1):

$$Y_{crt} = \alpha + \lambda_c + \lambda_r + \lambda_t + \rho D_{it} + X_{it}\delta + \varepsilon_{it} \quad (1)$$

where the dependent variable is (log) new car sales in city c in region r in year t . The unit of observation is at the city-region-year-model level in the first two panels, the month-year-model level in the third and fourth panels and the day-month-year-model level in the fifth and sixth panels. The dependent variable Y is the measure of "New Car Sales".

The fixed effects are treated as parameters to be estimated: c stands for city, r for region, d for day, m for months and y for years. The various λ terms indicate the fixed effects, and the vector X_{it} gathers the various control variables. D_{it} denotes the various treatments, and its parameter ρ is the object of the analysis, including, in some cases, its algebraic sign; ε indicates the error term.

The setup of the regression formula depends either on a temporal difference (times series analyses), which means that all the variables are observed before and after the introduction of car-sharing, or on a place-temporal difference (difference-in-difference analyses), which means that all the variables are observed before and after the introduction of car-sharing in various places.

The parameter ρ quantifies the size of the difference in explained variables before and after the launch of car-sharing between the treated variables and the control variables.

However, considering the possibility of autocorrelation between the independent variables—although mitigated by the presence of fixed effects—we investigated the statistical association between the dependent variables and the explanatory variables' coefficients. Finally, we added some controls, to which we assigned some theoretical importance, that may influence the explained variables. The data regarding the number of new car registrations were collected from the Italian Ministry of Infrastructure and

Transport (MIT) for the years 2010–17. The dataset contains information relating to vehicles registered in the National Vehicle Archive, managed by the Italian Driver and Vehicle Licensing Agency.

Table 1 summarizes the cities taken into account for the two difference-in-differences, as well as those that were used as controls, whereas **Table 2** contains descriptive statistics for the main variables. It should be noted that as control cities, we have used all other provincial chief-towns in the region in order to control for region-specific common features (e.g., policies implemented by regional governments). The selection of the control group may appear to be arbitrary; however, in the robustness checks in **Table 4**, we increase the comparability across cities by means of a weighting procedure.

Table 3 presents the difference-in-difference results for the effect of free-floating car-sharing's introduction on the number of new cars registered. The coefficients in columns (1) and (2) are negative and significant, as are the coefficients in columns (3) and (4). These findings indicate that an increase in the number of shared cars causes a decrease in the number of new cars registered. In particular, the log-log model quantifies that if the number of car-sharing cars available in a city increases by 1%, the number of new cars registered decreases by 3.42% in the same year, with all else being equal. Additionally, the lead model (F.) quantifies that if the number of car-sharing cars increases by 1%, the number of new cars registered decreases by 2.79% in the following year, all else being equal. These results are also confirmed by the *DiD treatment*—the car-sharing dummy—which is negative and significant at the 5% level in both the models.

The forward notation (F.) stands for one-year-forward observations, as compared to the other set of variables. It is reasonable to believe that the decision regarding whether to buy a new car occurs not directly after but some time after car sharing has been adopted.

Table 4 presents the regression results after the implementation of entropy balancing through the Stata command “*ebalance*”, which generated dynamic weights (“*_webal*”). This function of multivariate reweighting was depicted by Hainmueller (2012) and serves to generate balanced samples that are useful in analyses characterized by binary treatments. The weights assigned to the control cities make them more similar and allow them to be compared with the treatment cluster.

The treatment coefficients depicted in the balanced regression remained qualitatively meaningful and statistically significant at the 1% level in the normal setup, as well as at the 5% level in the lead setup. From an economic point of view, the coefficients' magnitude is even enhanced, resulting in a stronger effect on the balanced framework.

Conclusion

The need to pursue improvements in quality of life for urban citizens is driving considerable changes in mobility patterns, the composition of the vehicle fleet and even modes of transport. Bike- and car-sharing services seem to play a pivotal role in transport policymaking. In particular, the introduction of the car-sharing service is considered efficient because the more intensive use of vehicles would lead to a negative economic and environmental impact.

In this chapter, a brief literature review was presented with cases from around the world and a study was discussed to assess the short-run impact of the introduction of car-sharing in Italian cities in terms of new car sales. We have found that a 10% increase in the number of shared cars caused a 2%–3% reduction in the number of new cars registered in the city, implying a certain effectiveness on the part of car-sharing in reducing the car ownership rate and, hence, in the long run, the size of the car fleet.

This article shows that the total number of vehicles in a city can be reduced through car sharing system. This result is important in the long term, since it creates a reduction in the amount of land and infrastructure needed for parking, open up more space for development reducing the spatial footprint of a city. Car sharing can eliminate parking concerns without requiring a total abandonment of own cars. Since free-floating car sharing involve access to public parking spaces, they are more dependent on the support of local authorities. To increase the incentives for car sharing, the government needs information regarding the scale of impact of car sharing on new car registration. This article is an empirical contribution in this branch of research.

Both the literature and the case study presented in this article point at positive effects of car sharing in terms of travel distance and car ownership. Although these results cohere with the expectation that sharing mobility decreases the car ownership rate, they must be taken with caution because they provide only short-run evidence. As the effect of car-sharing in the long run remains largely unknown, further research on this topic is needed to corroborate or reject the underlying rationales for policy intervention in the field of car sharing.

Evaluation Methods in Transport Policy and Planning

Transportation networks provide an array of benefits in the forms of goods delivery, access to services and personal mobility. However, transport can also result into several adverse effects such as damages to nature reserves, CO₂ emissions and noise pollution. Governments are in many ways involved in transport policy and planning. For instance, they determine regulations such as speed limits and they can decide to invest public budget in the extension and/or maintenance of transport infrastructure. In many cases, policy makers want to decide informed by the expected positive and negative impacts of a transport policy option. Various ex-ante evaluation methods are available which can be used to provide such information. This article surveys five evaluation methods that are used in transport policy and planning: Cost–Benefit Analysis (CBA), Participatory Value Evaluation (PVE), Multicriteria Analysis (MCA), Environmental Impact Assessment (EIA), and the Social Impact Assessment (SIA). The five methods will be introduced, and differences will be described.

Cost–Benefit Analysis

In virtually all western countries CBA is mandatory when national funding is asked for large transport projects (Mackie et al., 2014). A CBA measures the social desirability of a transport policy option in a systematic way based on economic theory. CBA quantifies the project's positive and negative effects and translates these quantified effects in monetary terms. Next, these monetary impacts are presented as present values using a discount rate which accounts for the notion that people prefer present impacts over future impacts (Mouter, 2018). Finally, present values are aggregated into a final indicator such as the net present value (NPV).

Welfare economics provides the theoretical underpinnings of CBA (Boadway and Bruce, 1984). One of the key concepts in welfare economics is the Pareto criterion which entails that the social welfare effect of a project is positive if it makes someone better off without making anyone worse off (Nyborg, 2012). A problem is that government policies will hardly ever be able to pass this criterion. For instance, when considering new transport infrastructure, taxpayers will pay the costs, and quite probably there will be negative external effects, for example noise or CO₂ emissions. A more practical concept is the Kaldor–Hicks efficiency criterion, which relaxes the Pareto conditions by adding the possibility of (potential) compensation. The Kaldor–Hicks efficiency criterion asserts that a policy (or other change) can be considered as welfare increasing if those who benefit can compensate those who suffer from it, creating a Pareto improvement after compensation. According to the Kaldor–Hicks efficiency criterion, the compensation does not actually have to take place: it is enough that it is theoretically possible. This implies that there is only a potential Pareto improvement, and not necessarily an actual Pareto improvement. Standard CBAs are generally based on the Kaldor–Hicks efficiency criterion. CBA assesses whether a transport project passes the Kaldor–Hicks efficiency test by expressing all the positive and negative effects of a policy in monetary terms and adding them up. If the sum is positive the project is considered to be welfare enhancing as those who benefit can theoretically compensate those who suffer.

Welfare economics provides strict procedures for the objects that have standing in the CBA analysis, for the impacts that are considered in the analysis and for the way different impacts are valued. In principle, welfare economics prescribes two principles when conducting a CBA being individualism and non-paternalism. Individualism implies that the preferences of individual citizens form the basis of a CBA (Sen, 1979) and nonpaternalism entails that individuals are conceived to be the best judge of their own welfare. In combination these postulations imply that the citizens and firms that are affected by the policy are the sole objects who have standing in a CBA study and their preferences are respected. In principle, preferences of experts, stakeholders and policy makers related to the impacts of the transport project do not play any role in the analysis as these actors are only consulted to provide methodologies for deriving the preferences of citizens. Welfare economics also provides CBA researchers with a clear frame of reference when selecting the impacts of transport policy options that should (not) be included in a CBA because only impacts that

affect the welfare of individuals should be included. For instance, citizens' preferences for the way that the benefits and burdens of a transport policy options are distributed across society are not part of the total net benefits in a CBA (Mouter et al., 2017a). Another consequence that is excluded from a CBA is public support for a transport policy option (Mouter, 2017).

Welfare economics also provides clear guidance for the weighting procedure that is used in CBA to evaluate the impacts of a transport policy option. CBA measures a project's societal value by transferring the project's societal effects in monetary terms using the notion of the amount of money individuals are willing to pay from their private income. For a positive effect, the WTP is the maximum amount which a person is prepared to pay for it. For negative effects, the willingness-to-pay is negative (then often called willingness-to-accept). For instance, the most dominant approach to derive the amount of money that individuals are willing to pay for reductions in travel time and accident risk relies on (hypothetical) route choice experiments in which travellers are asked to make a series of private choices between routes which differ in terms of travel time, accident risk and travel costs (e.g., Hensher et al., 2009). Impacts of transport policy options on landscape, nature and noise pollution are evaluated through analyzing the private decisions of individuals in the real estate market (e.g., Allen et al., 2015).

Participatory Value Evaluation

A core postulation of the CBA is that impacts of transport projects financed by the government are valued based on the amount of money individuals and parties are willing to pay from their private income. However, a range of scholars argues that the way in which individuals balance their own money against the attributes of government projects may substantially differ from the way that these individuals believe that their governments should trade-off public budget and impacts of public projects (e.g., Ackerman and Heinzerling, 2004; Sagoff, 1988). These academics believe that the amount of money individuals are willing to pay from their after tax income in (hypothetical) route choices provides crucial information for a toll company to determine the price that travelers should pay that want to use the road. In addition, these scholars accept that a real estate agency uses past choices from individuals in the real estate market to estimate a price for which houses in a new real estate project can be sold. However, the above-mentioned academics assert that the private WTP valuation paradigm fails to consider that private choices may not fully reflect citizens' preferences towards public policy.

The divergence between people's preferences in a private choice setting and a public choice setting has been recognized by various transport scholars. For instance, Mackie et al. (2001) argue that there is no good reason for the value that the individual is willing to pay to reduce travel time to be equal to the value that society at large attaches to the reassignment of time of that individual to other activities. Moreover, Jara-Díaz (2007) observes that there can be a stark difference between the values for use in public sector appraisal and the values which a commercial operator would wish to use in an analysis of the same project. The literature points out several reasons why it is problematic to infer the welfare of a government policy through individuals' private willingness to pay in the context of private consumer choices; (1) People may not be willing to contribute individually because the impact of their individual contribution is imperceptible, but people may be willing to contribute when the whole community is forced to contribute through a government intervention because the aggregate impact of this coordinated contribution can be substantial (Sen, 1995); (2) People value the same impact differently in a private sphere (grocery store) and a public sphere (ballot box) as moral considerations might be more salient in the latter context (e.g., Sagoff, 1988); (3) Valuing impacts of a government project through observing their consumer choices ignores that people may place a value on the way collective decisions are made.

Scholars developed so-called willingness to allocate public budget experiments (WTAPB) to alleviate the issues addressed above (e.g., Mouter et al., 2017b). In WTAPB experiments individuals make choices over alternative allocations of government budget across different government projects. The WTAPB approach thus aspires to infer welfare effects of (impacts of) government projects from individuals' preferences regarding the expenditure of public budget. The most important benefit of the WTAPB valuation approach is that individuals who believe that government budgets should be spent on different purposes than their own money can express these preferences (Mouter et al., 2020). A second advantage of the WTAPB valuation approach is that it bypasses the concern that WTP-based valuation is an inappropriate way to value impacts of government projects that are relatively difficult to translate into private income examples being landscape and nature. WTAPB does not require translation of government project impacts into private income. Instead, an impact of a government project is valued through the extent to which individuals are willing to sacrifice other impacts of government projects (Mouter et al., 2020). For instance, in a WTAPB experiment, individuals are asked to trade-off noise pollution against other impacts of governmental policy (e.g., reduction of mortality risk) which contrasts the WTP valuation approach in which individuals are asked to trade-off environmental impacts against private income. Moreover, the other two issues with the private WTP paradigm addressed in the previous paragraph ("people may be willing to contribute collectively, but may not be willing to contribute individually" and "people may place a value on the way collective decisions are made") are addressed in a WTAPB setting because impacts of transport projects are valued in a collective setting in which overall burdens and benefits of proposed transport projects are considered together in the context of a government decision (Mouter et al., 2019).

Although the WTAPB approach ameliorates various critiques of the private WTP valuation paradigm adopted in standard CBA, one clear downside of this valuation approach is that respondents are forced to spend the public budget as they have to make a choice between two or three alternative allocations of public budget. Therefore, preferences of individuals who believe that it is better to do nothing and/or reduce taxes instead of allocating public budget to one of the proposed projects are not respected. Participatory Value Evaluation (PVE) is a valuation method which has been developed to address this limitation of WTAPB. PVE establishes the desirability of government projects based on an experiment in which individuals select their preferred portfolio of government

projects given a constrained public budget (Mouter et al., 2021). The crucial difference between PVE and WTAPB is that participants in a PVE have the option to advise the government against allocating the budget to any (or some) of the projects that are considered in the PVE and shift the remaining budget to the next year (Mouter et al., 2020).

Recent literature on PVE distinguishes between two variants of PVE-experiments. First, the “fixed budget PVE format” which allows participants to allocate an earmarked amount of public budget and/or shift the public budget to the next year. To provide a stylized example of a “fixed-budget” PVE-experiment, assume that respondents can allocate a budget of 8 million euro to 16 projects all costing 1 million euro. In this context, respondents can allocate the budget to 8 or less projects. The second type of PVE experiment is called “the flexible budget PVE format”. In this format, participants are also allowed to change the public budget which will imply a change in taxes thereby affecting their after-tax income. In our stylized example participants would also be allowed to decrease the budget to, for instance 0 and this would imply an increase in private income through a reduction of taxes. On the other hand, respondents can also increase the budget which allows them to select more or even all the 16 projects. However, this would result in a tax increase and a reduction in their private income. Another difference between WTAPB experiments and PVE is that participants in a PVE allocate public budget to a portfolio of projects and, as a result, they can consider positive and negative synergies between projects and potential spatial equity concerns (Mouter et al., 2021). This is not possible in a WTAPB experiment where respondents select only one project from a limited set of projects. Hence, PVE allows individuals to express a broader set of preferences than WTAPB experiments (e.g., positive and negative synergy effects, preferences of individuals who believe that it is better to do nothing and/or reduce taxes instead of allocating public budget to one of the proposed projects).

The innovations of the PVE appraisal method are described in various papers (Dekker et al., 2019; Mouter et al., 2020, 2021). Mouter et al. (2021) explain that PVE can not only be considered as a valuation method which provides input for a CBA, but that the outcomes of a PVE can also be directly used for establishing the social welfare effects of government policy options. In that case, PVE can be considered as a full-fledged alternative to CBA. Dekker et al. (2019) present the technical details of such a welfare analysis. Mouter et al. (2021) also establish the extent to which CBA and PVE provide different policy recommendations and finally they aim to generate empirical insights into potential reasons why PVE and CBA produce different outcomes.

At present, only one large scale PVE has been conducted for the evaluation of transport projects (Mouter et al., 2021). In this PVE 2498 inhabitants from the Transport Authority Amsterdam were presented with 16 transport projects and related societal impacts. The total costs of the 16 projects was 386.5 million euros but with only 100 million euros to spend, it was not possible for the respondents to include all projects in their portfolio. A link to the demo version can be found via www.burger-begroting.nl and an English language version is available via <http://burgerbegroting.tbm.tudelft.nl/participatory-value-evaluation-transport-authority-amsterdam>. Mouter et al. (2021) show that in a PVE the societal value of transport projects is estimated using behavioral choice models which assume that participants aimed to select a portfolio of transport projects that in their view represents the portfolio which maximizes their “utility”. It is assumed that part of the value of an individual project is defined by the impacts that were explicitly presented to participants for each of the transport projects (e.g., reducing travel time, change in the number of traffic deaths) which is reflected in taste parameters (this is comparable to stated choice surveys which estimate the value of travel time savings and the value of a statistical life). Moreover, it is assumed that the (un)attractiveness of an individual project can also be defined by other considerations which is captured in project specific parameters. The authors find that projects which focus on improving traffic safety perform relatively good in the PVE, whereas car projects perform relatively good in the CBA analysis.

Multicriteria Analysis

The MCA, also known as multiple-criteria decision-making (MCDM) or multiple-criteria decision analysis (MCDA) typically encompass the following stages: (1) identification of criteria against which to test transport policy options; (2) weighting or scoring the different criteria to arrive at a ranking of options. A deep variety of MCA methods has been developed over the last years (Dean, 2018). A certain class of MCA approaches can be defined by the set of rules establishing the nature of options, objectives, criteria, scores and weights as well as the way in which objectives/criteria, scores and weights are used to assess, compare, screen in/out or rank options.

A distinction can be made between “sophisticated MCA methods” and “simple MCA methods”. Sophisticated methods use advanced mathematical principles and procedures to weigh criteria and rank options. One example of such a method is the Analytic Hierarchical Process (AHP) (Saaty, 1990). AHP begins by arranging the elements of the analysis in three main hierarchical levels. The overall goal of the decision-making problem at the top (e.g., satisfaction with a transport policy option); a set of decision criteria in the middle layers (e.g., factors that influence the satisfaction of transport policy options); and a group of competing options at the bottom (e.g., transport policy options). Next, the relative importance of each criterion with respect to the goal of the analysis is determined through a series of pairwise comparisons of criteria. The subjective judgments of experts or policy makers regarding the relevance of the different criteria are translated into a quantitative score and subsequently the most desirable option can be determined. Another example of a sophisticated MCA technique is the best-worst method (BWM) developed by Rezaei (2015). Similar to AHP, the BWM method starts with determining a set of decision-criteria. A key difference with AHP is that in the second stage decision-makers participating in a BWM are asked to select the best and the worst criteria after which they should determine the preference of the best criterion over all the other criteria and the preference of all the other criteria over the worst criterion. Based on these choices both the direction and the strength of the preferences of one criterion over the other are computed which provides the basis of selecting the best alternative.

Simple MCA methods use relatively rough procedures to score options or even abstain from scoring and ranking the options. One example is the UK Appraisal Summary Table which does not aim to provide a final ranking of the options. Simplified MCA techniques are very popular, mainly due to practicality reasons (Dean, 2018). MCA studies can be undertaken either in nonparticipatory (i.e., expert-led) or participatory manner. In nonparticipatory assessments, the analysis is carried out autonomously by one or more experts, according to a typical technocratic approach. A key argument in favor of this approach is that a group of scientists and trained experts is better suited to make complex decisions than the average citizen. By contrast, participatory techniques adopt a more collaborative decision-making style, with the direct involvement of the different interested and affected parties (i.e., problem stakeholders) in the analysis (Macharis and Bernardini, 2015). Although participatory MCA techniques have been championed by transport scholars in the literature it is not totally clear whether techniques have enjoyed real-world applications or constitute mere academic proposals (Dean, 2018).

CBA, PVE, and MCA are quite similar in several respects. The three appraisal methods all aim to provide policy makers with information to assess the desirability of a transport policy option and the methods all rely on transportation model results. The most important difference between CBA and PVE on the one hand and MCA on the other hand is that welfare economics provides the theoretical framework underlying CBA and PVE, whereas MCA methods are not built on this theoretical framework. CBA and PVE are both based on welfare economics which provides strict procedures for the objects which have standing in the CBA analysis, for the criteria/impacts that are considered in the analysis and for the way different impacts are valued. MCA analysts, on the other hand, have a larger degree of freedom when selecting criteria and developing procedures to determine the weights (e.g., Macharis and Bernardini, 2015). For instance, a MCA analyst can decide to include distributional aspects and public support for a transport policy option as separate criteria which affect the final outcome of a MCA. Both impacts cannot affect the final indicators of a CBA that is grounded in the Kaldor–Hicks efficiency criterion. PVE assumes that individuals define the attractiveness of a transport policy option based on standard impacts of a transport project such as reductions in travel time and accident risk (which are reflected in taste parameters) as well as other criteria that might not be on the radar of policy makers and experts (which are reflected in project specific parameters). Hence, PVE includes distributional impacts such as spatial equity (Mouter et al., 2021) and there is no fundamental difference between PVE and MCA when it comes to the inclusion of impacts in the evaluation.

Moreover, the weighting procedure that is used in CBA to evaluate the impacts of a transport policy option is very clear in the sense that the only criterion that defines the weight that should be assigned to an impact concerns the amount of money individuals are willing to pay from their private income. The same holds for a PVE in the sense that transport policy option are valued based on the willingness of individuals to allocate public budget to (the impacts of) the transport policy option. The weighting of impacts/criteria in a MCA can be partly based on translating impacts/criteria into monetary units, but the aggregation is also based on at least one other weighting method (e.g., scoring, ranking or weighting of a wide range of qualitative impact categories and criteria).

In sum, the three methods differ in terms of degrees of freedom for the analyst to select impacts and criteria that are relevant for the evaluation as well as weighting procedures. A CBA analyst has to follow strict procedures of welfare economics when selecting impacts and weighting procedures and as a result the degrees of freedom are limited; a PVE analyst has more liberty when selecting impacts although participants in the PVE (and not the analysts) eventually determine the relevance of a criterion for the evaluation. As stated above, a PVE analyst has no degrees of freedom when selecting a weighting procedure. Finally, a MCA analyst has large degrees of freedom in terms of selecting impacts and weighting procedures. The relatively large degree of freedom can be seen as a strength of MCA when benchmarked against CBA and PVE. For instance, Gühnemann et al. (2012) asserts that MCA seems to be better in measuring intangibles and soft impacts than CBA as these effects do not have to be converted into private income. For this reason, MCA has been used in many countries as complementary to CBA to capture impacts not properly accounted for by the latter method (e.g. Mackie et al., 2014).

Although the flexibility of MCA can be seen as a strength, this characteristic of the evaluation method has been criticized for the arbitrariness in the selection of the weights applicable to different criteria (Annema et al., 2015). Qualitative assessment and the imputation of value-laden weightings to different criteria may lead to subjective biasing. This arbitrariness in MCA has often been used by politicians to justify already preadopted decisions, which has undermined the rigor of the MCA appraisal method (Dobes and Bennett, 2010).

Environmental Impact Assessment

An Environmental Impact Assessment (EIA) is a comprehensive evaluation of the likely effects of a project that significantly affect the environment. It provides decision makers with an indication of the likely environmental consequences of their selected policies (Jay et al., 2007). Since the 1970s EIA has become increasingly more important in planning practice and has been introduced in national legislation worldwide (Cornero, 2010). Due to the legal requirements for EIA implementation, there are now strict guidelines for the EIA process (Cornero et al., 2010). The usual information contained in an EIA report is: (1) a description of project alternatives and a baseline description of the environment where the project is located; (2) a prediction of potential effects of the project on the environment; (3) measures envisaged to avoid, prevent or reduce the effects on the environment. The most important differences between EIA and the three methods that were previously discussed (CBA, PVE, and MCA) is that the EIA puts emphasis on a specific set of effects (environmental effects). A second difference is that an EIA also includes recommendations regarding the mitigation and management of negative environmental impacts. The purpose of the other methods that were discussed is not to provide such recommendations.

Social Impact Assessment

Social Impact Assessment (SIA) was introduced in the late 1970s in the United States due to the perception of EIA being an assessment method with a strong biophysical bias (Morgan, 2012). The primary purpose of a SIA is to bring about a more sustainable and equitable biophysical and human environment (Vanclay, 2003). A SIA includes the processes of analyzing, monitoring and managing the intended and unintended social consequences of planned interventions (e.g., Mottee and Howitt, 2018). Vanclay (2003) describes the core values of the SIA community and a set of principles to guide SIA practice. The role of SIA goes far beyond the ex-ante (in advance) prediction of adverse impacts and the determination of who wins and who loses (Vanclay, 2003). Esteves et al. (2012) argue that SIA practitioners also believe that there should be an emphasis on enhancing the lives of vulnerable and disadvantaged people, and in particular, that there should be a specific focus on improving the lives of the worst-off members of society. Hence, the normative postulations of SIA are more in line with Rawlsian ethics which differs from the utilitarian philosophy which undergirds CBA.

SIA is an anthropomorph methodology in the sense that analysts consider all issues that affect people. The main difference with CBA (and PVE) is that all social impacts are considered in a SIA and not only to the extent that humans are willing to pay (or willing to allocate public budget) for the impacts of the transport project. As a result, the degrees of freedom for the analyst to include impacts is relatively large likewise the MCA.

SIAs utilizes participatory processes to analyze the concerns of interested and affected parties. It heavily involves stakeholders in the assessment of social impacts, the analysis of alternatives, and monitoring of the planned intervention. The role of stakeholders in the analysis is much larger compared to the other evaluation methods discussed. MCA and EIA aim to involve stakeholders more and more, but stakeholder participation is an end of SIA in itself (Esteves et al., 2012). A typical SIA consist out of various steps examples being the identification of interested/affected people, selecting alternatives, assessing the social impacts, developing mitigation measures, developing strategies for dealing with residual or nonmitigatable impacts and proactively developing better outcomes (Vanclay, 2003). Hence, the focus of concern of SIA is a proactive stance to development and developing better outcomes, not just the identification or amelioration of negative or unintended outcomes.

Conclusion

This article surveyed five evaluation methods that are used in transport policy and planning: Cost-Benefit Analysis (CBA), Participatory Value Evaluation (PVE), Multi-Criteria Analysis (MCA), Environmental Impact Assessment (EIA) and the Social Impact Assessment (SIA). The main difference between the CBA and PVE is that PVE establishes the desirability of government projects based on people's advises regarding the allocation of the public budget toward (impacts of) government projects, whereas CBA establishes the desirability of government projects through analyzing people's trade-offs between their private income and impacts of government projects. The most important difference between CBA and PVE on the one hand and MCA on the other hand is that CBA and PVE are both based on welfare economics which provides strict procedures for the criteria/impacts that are considered in the analysis and for the way different impacts are weighted, whereas MCA analysts, have a larger degree of freedom when selecting criteria and developing procedures to determine the weights. The most important difference between EIA and SIA and the other three methods is that EIA and SIA put emphasis on a specific set of effects (environmental or improving the lives of the worst-off members of society). A second difference is that an EIA and SIA also include recommendations regarding the mitigation and management of environmental and/or social impacts.

Biography

Niek Mouter is an assistant professor in Infrastructure Project Appraisal at Delft University of Technology, the Netherlands, faculty Technology, Policy and Management. His research primarily revolves around two research lines: (1) The inclusion of equity and other ethically important considerations in the appraisal of infrastructure projects in general and Cost-Benefit Analysis in particular; (2) Improving the usability of Cost-Benefit Analysis for policy makers. He (co)developed a novel assessment approach called 'Participatory Value Evaluation'.

Introduction

Transport systems are capable of producing significant benefits; however, they have produced over previous decades many negative externalities. For that, appropriate policies need to be devised to maximize its benefits and minimize its inconveniences. In urban areas, although many contributory sources to air pollution exist, road transport, in particular, continues to account for a significant proportion of emissions of all the main air pollutants (with the exception of SO_x) which has increased overtime. In 2017, in Europe the non-exhaust emissions of PM_{2.5} accounted for 46% of emissions from the road transport sector, compared with 18% in 2000, while for PM₁₀, the contribution increased from 32% in 2000 to 63% (EEA, 2017). In the UK, transport is responsible for approximately half of the NO_x emissions. In addition, these emissions tend to be emitted close to where people live and work, making the potential health impact even greater, by increasing the population exposure to higher levels. While emissions from road transport are mostly exhaust emissions arising from fuel combustion, including volatile organic compounds (VOCs), carbon monoxide (CO), and hydrocarbons (HCs) contributing to the formation of ground-level ozone and photochemical smog in the atmosphere, non-exhaust emissions contribute to both NMVOC (from fuel evaporation) and primary PM. An important consideration related to PM nonexhaust pollution in particular is that road transport contributes also from tyre- and brake-wear and road abrasion, which will still be generated even shifting 100% into ultra-low carbon vehicles such as full electric.

These two road-transport based particles sources make up 12% of the smallest and most dangerous type of PM, which can enter the bloodstream via the lungs. For Europe, the WHO estimate for the number of premature deaths attributed to air pollution is over 500,000 (WHO Europe, 2018), with 400,000 early deaths in the EU28. As a result, future strategies and policies should consider carefully the long terms benefits but more importantly the potential indirect or underestimated impacts. It is acknowledged that the allocation, design, and construction of transport infrastructure and services must be subject to careful planning, both by public and private agencies (Rodrigue, 2020).

The Role of Planning and Policies

First, a differentiation between policy and planning must be drawn, since the former usually relates to strategies and goals while the latter refers to concrete actions. Also, both must reflect the fundamental changes in society and contemporary issues and problems, hence policies and planning should constantly change.

- Transport policy deals with the development of a set of constructs and propositions that are established to achieve specific objectives relating to social, economic, and environmental conditions, and the functioning and performance of the transport system.
- Transport planning deals with the preparation and implementation of actions designed to address specific problems.

Over recent years, however, the strategic and wider impacts of planning choices have been difficult to capture, and overtime can cause additional elements of impact that year on year may result in air quality hotspots and local issues at pinch points.

There is no doubt that to plan for sustainable cities, we must consider the effect of transport policy on the environment in terms of air quality and its subsequent effect on health. As suggested by Engardt et al. (2011), there are various factors influencing air quality

within a planning horizon of 20–30 years: the global effect of climate change as well as local effects of urban form need to be considered. At the local level, the design of transportation systems and transport policies will influence the city's own contribution to air pollution. The travel choices made by inhabitants not only determine their contribution to urban emissions, but also influence their own health, which in turn determines the health sustainability of society as a whole. Empirical evidence from the last decade has shown that the characteristics of city and regional land use and transport planning are directly linked with air quality, individual exposure, uptake of pollutants and subsequent health outcomes. See for example [de Nazelle et al. \(2011\)](#), [Schindler and Caruso \(2014\)](#), and [Sider et al. \(2013\)](#).

It is important then, that local plans must commit to a compelling and clearly expressed place-based vision that has sustainable transport as well as health, climate change and environmental needs integrated from the start. Also, strategic and local plan producers must create collaborative partnerships with strategic stakeholders, transport service providers, and local communities going beyond statutory consultation ([CHIT, 2019](#)).

Links Between Transport Planning, Policies and Air Quality

Within cities can be observed considerable variation in the levels of environmental exposures to air pollution, noise, temperature variations and green spaces. Emerging evidence ([Nieuwenhuijsen, 2016](#)) suggests that urban and transport planning indicators such as road network, distance to major roads, and traffic density, household density, industry and natural and green space explain a large proportion of that variability. Personal behavior, including mobility, adds further variability to personal exposures, determines variability in green space and exposure, and can provide increased levels of physical activity.

Decision-makers need not only better data on the complexity of factors in environmental and development processes affecting human health, but also enhanced understanding of their linkages to be able to know at which level to target their actions. New research tools, methods and paradigms such as geographical information systems, smartphones, and other GPS devices, small sensors to measure environmental exposures and remote sensing are expected to provide crucial information for next generation of data driven plans and policies. Same data are expected to provide rich sources for the depth assessment of impacts and exposure, using new approaches such as the exposome paradigm ([Vrijheid, 2014](#)) together with citizens and cities observatories information.

While in cities there are often silos of urban planning, mobility and transport, parks and green space management, environmental management (public) health departments that tend to work largely independent and rarely together, multisectorial approaches are needed to tackle the environmental problems ([Gerike et al., 2016](#)).

For example, [Olowoporoku et al. \(2010\)](#) used a longitudinal study of the links between Local Air Quality Management and Local Transport Planning policy processes in England and observed that while substantial improvements in policy integration were happening within the selected case studies, it demonstrated that such improvements are often constrained by institutional complexities that create implementation gaps between national objectives and local decision-making outcomes.

New Concepts, Methods and Tools to Provide New Insights

In this section, the aim is to provide some inspiration looking at two alternative and innovative methods that recently have been proposed respectively to improve the Planning and Policies to achieve more sustainable and low polluted cities.

Exposome Paradigm

To get away from studying the “one exposure, one health outcome” associations, the new paradigm of “exposome” has been developed by [Vrijheid et al. \(2014\)](#). The paradigm envisages complex multilevel pathways and interactions with other environmental, socioeconomic, social, behavioral and life-style factors, and genetics. The exposome encompasses the totality of human environmental (i.e., nongenetic) exposures from conception onwards, complementing the genome ([Wild CP, 2005; 2012](#)). The dynamic nature of the exposome presents one of the most challenging features of its characterization. The increased use of new technologies including geographical information systems (GIS), sensors, remote sensing, combined with more traditional approaches has made possible to start assessing the exposome theory. First attempts have been made in large European projects such as HELIX (<http://www.projecthelix.eu>), EXPOSOMICS (<http://www.exposomicsproject.eu>), and HEALS (<http://www.heals.eu>).

The PASTA Project

The Physical Activity Through Sustainable Transport Approaches EU project, completed in October 2017, by using a mixed-method and multi-level approach that review interventions to improve outdoor air quality and public health, supported the development of policies aiming at increasing the physical activity of European citizens in the urban environment. Those resulting policies were consistently tested and applied in seven case study EU cities. A large-scale longitudinal survey involving 14,000 respondents was also carried out to assess the health impact of active mobility, with the final goal to inform the WHO's online Health Economic Assessment Tool for the health benefits of cycling and/or walking ([Gerike et al., 2016](#)).

Modeling

From a modeling point of view, a planning model should support the analysis of the effectiveness of policy decisions in terms of different aspects, such as environmental, economic, and health impact, taking into consideration users behavior response and its subsequent effect on the environmental and public health.

In the past, different studies have tried to link strategic transport planning models with air quality models, for example, [Affum et al. \(2003\)](#), [Boogaard et al. \(2012\)](#), [Hatzopoulou and Miller \(2010\)](#) or quantify the health impacts from transport related physical activity as well as changes to air pollution in [Woodcock et al. \(2013\)](#) applying an Integrated Transport and Health Impact Modelling Tool (ITHIM). More recently promoting smart, green and integrated transport has become the key priority in the strategic move towards sustainable development by the European Union and many other countries worldwide. This is reflected by the numerous studies on designing, modeling and promoting green transport systems (e.g., [Bao et al., 2017](#); [Kitthamkesorn et al., 2016](#); [Lin and Liao, 2016](#)); also, environmental constraints and efficiency as well as sustainability have been considered explicitly in many transport network design studies (e.g., [Li et al., 2014, 2016](#); [Maheshwari et al., 2016](#); [Yang et al., 2017](#)).

This however, has gradually changed the traditional and general approach taken by most transport planning and air quality models, where traffic information from the transport planning model, including traffic flow, speed and vehicle types on each roadway, are taken as input into air quality models. However, this traditional approach has shown in recent years several limitations and modeling usually represents scenarios based on assumptions and over time those assumptions can change drastically, requiring new model inputs and settings. Emerging approaches, such as the Agent-based modeling tools seems to go on the right direction and provide the right flexibility of the approach to be quickly adapted to changes.

Moreover, with recent pandemic events, also, more than ever, integration of planning, strategies and air quality modeling should aspire to solve and embed some of the existing identified gaps ([Wang and Connors, 2018](#)):

1. Wider access to health impact metrics;
2. The existing health impact should include both physical activity benefits and pollutant uptake;
3. Include localized effect on spatial pattern of air quality as a result of transport choices of residents;
4. More accurate exposure encountered by travelers on different modes at different locations throughout their trip; and
5. Exposure estimated based on a combination of users physical activity associated with different modes as well as the spatial pattern of air quality concentrations.

Those gaps have become particularly important since the development of the recent COVID-19 pandemic, which is likely to change in the long-term people behavior and the way we all work and live. This will have implications on the assumptions made on modeled scenarios for the next 5–10 years, which will definitely require a revisit and reassessment exercise. Similarly unexpected behavioral changes will emerge that may affect user choices, from the purchase of the house in more rural areas, to the impact on times and volumes of movements impacting the transport network.

The “New Normal”, Opportunities and Potential Impacts

As anticipated, recent events (COVID-19 pandemic), have definitely accelerated transitions that may have happened anyway or introduced completely new behaviors which will have a huge impact over next 5–10 years, such as massive increase of on-line shopping and remote working, the latter also causing unprecedented reduction of patronage in the public and shared transport, that although may be temporary may have a huge impact on the use of private motorized modes and hence increase of air quality problems, particularly in urban areas and occasionally in suburban areas and towns.

Another interesting emerging evidence is related to the impacts of the pandemic and lockdown on traffic volumes and economy. If we take as an example the UK, we have observed that although there was a visible large reduction of traffic volumes in April 2020, around –75% ([WAZE, 2020](#)), the economic impact within the same period has been –20.4% ([ONS, 2020](#)). Although 20% economic shrink was unprecedented, it is very interesting to observe the huge difference in the two reductions. This suggests that not all traffic on our roads was and is responsible or contributing to the economic growth and directly support the economy, but actually may contribute heavily to increase pollution and worst air quality without actually producing tangible economic benefits.

This is why it is important in the future to better understand and link transport movements to economy and identify those elements (e.g., commuting trips) that if removed (via remote working) will not impact the economy almost at all but produce enormous benefit especially in terms of urban pollution and overall transport GHG (Green House Gas) emissions. This capability should be embedded into future integrated models to allow a more holistic view and assessment of the benefits and costs both economic and environmental.

Active Transport and Planning Role

Before recent events, many studies and policies have suggested that more active travel such as walking and cycling would be beneficial to reduce short distance trips hence reduce local pollution and carbon emissions, but limited uptake in the large majority of cities and towns was observed. However, since March 2020 more and more frequently we have observed positive changes in terms of behavior of commuters and citizen. After the various lockdown and pandemic events, many people have started to consider and

move using active transport, making enormous progress in the shift towards this type of mode. In particular, while public transport is still subject to restrictions for social distancing, active transport choices in cities and towns need to be carefully planned and implications considered, in particular in terms of safety and security, generating virtuous circles. For example, a more pleasant roadside environment encourages walking and cycling. If more people choose to walk or cycle instead of drive, air pollution goes down and with it comes more demand for active travel infrastructure.

Planning then becomes a very important factor in the shift of citizens behaviors and choices, and the current situation offers an unprecedented opportunity to accelerate this process and make sure at planning and policy levels active transports are encouraged and prioritized, but that requires also a rebalance of the mobility infrastructure investment.

As indicated in the modeling section, in order to make sure models can truly represent the cost and benefit of the different choices including factors such as exposure, physical activities and long-term impacts of air pollution will help, especially in the long-term, to prioritize the best and more environmentally/sustainable form of transport systems and supporting infrastructures.

A final consideration is that among all modes of transport, active travel options are truly carbon free, while ultra low carbon or zero-carbon modes and options (electric vehicles, hydrogen, etc.) may have low carbon emissions at tail-pipe but they have embedded carbon that in most cases can offset the local benefits. For that many studies are suggesting an increasing importance of accounting for whole life carbon emissions to compare the greenhouse gas emissions among different options of low carbon vehicles and modes. Knobloch et al. (2020) for example have highlighted that based on a global average, and on current trajectories (half of all cars on the road could be electric vehicles by 2050), electric vehicles would achieve a 30% reduction in emissions per kilometer traveled, with this saving expected to increase as the adoption of renewable energy technologies grows. This, although is an important reduction, shows that to achieve net-zero carbon targets by 2040 or even 2050, policies and planning need to work together to make sure truly zero-carbon options such as active travel are facilitated and thought since the planning stage.

Conclusions

To conclude, this contribution has tried to highlight how transport and air quality planning and policy cannot anymore be separated and to truly achieve important and consistent results in the long-term, we all need to consider the different levels of complexity from large to local scale analysis and impact assessment. This ability in some ways does not exist currently and national authorities should focus on supporting initiatives that can develop and validate integrated approaches where planning, policies and impact assessment are equally important. It is acknowledged that this is not an easy task, but it is a key step that needs to be initiated to make sure truly sustainable and healthy cities will exist in a near future.

Biography

Dr. Fabio Galatioto is Senior Transport and Environmental specialist at Connected Places Catapult. Fabio has background in Transport Engineer and Modeling with almost 20 year experience in Transport and Environmental Monitoring and modeling, Air Quality, Sustainability & Impact Assessment and Traffic Safety. Since joining the Catapult in 2015 Fabio has been working to support SMEs and Academic partners and deliver innovative transport and environmental projects both at National and European Level.

Historical Background

The history of cycling for transport is not geographically homogeneous, but there were some important events that happened in specific places in the US, the UK and other countries in Europe that influenced mobility at a global scale. Cycling policy probably started in the last quarter of the 19th century; when cycling spread all over the world and began to be used for mobility more than just for sports and leisure. Towards the end of that century, bicycles became affordable enough to reach the middle-classes and even played an important role in social movements such as the women's suffrage movement. At the same time and within very similar groups of users, cycling was critically contributing to the birth of the motoring industry transferring its knowledge in mechanical design and literally paving the way for the cars to arrive and spread all over the world (Reid, 2015). Around 1920s, motor cars arrived, and cycling became the poor people's transport. Thus started the era of automobility, the dominance of the motor car, not only for transport, but also as a social, economic, and cultural icon (Pooley, 2020). "Peak bicycle" in many cities happened between the 1930s and 1950s, variations depending on the impact of World War II (and other conflicts, such as the Spanish Civil War) in automobile and bicycle supplies. Some European cities' maps of the 1930s include cycling infrastructure, acknowledging that cycling was integrated in transport planning (Oldenziel et al., 2016). After the war, cars took over the streets very quickly, becoming especially prominent in wealthy cities and countries where the automobile industry flourished.

But in some places, cycling continued to be fully present as a mode of transport. These were places where economic resources were not sufficient for a notable uptake of cars (some big cities in the global south had a prominent use of bicycles until the 1990s) or where disruptive economic events and social movements created "perfect storms" against the hegemony of the car. In these places, cycling approaches were integrated back again in transport policies, but these were not easy nor rapid processes. These were the cases of The Netherlands and Denmark where cars took over from the 1950s until the early 1970s when automobility was disrupted by the energy crisis (1973) and questioned by civil society. The pressure of social movements was especially prominent in Amsterdam, in response to the high number of children killed in traffic crashes. Even in these cases, proper official cycle planning only arrived more than a decade later, in the 1980s. The remains of the 1930s cycling infrastructure were the starting point in Copenhagen and from there, cycling provision and practice increased until present times (Oldenziel et al., 2016).

Due to their specific historical contexts, "cycling paradises" in Denmark and The Netherlands might have a longer tradition of cycling policy than other places but it is not completely clear yet what should be done in other places to obtain similar cycling mobility levels.

What are Cycling Policies About?

Cycling policies are about cycling mobility. The term mobility is preferred to transport, with the aim of moving beyond the traditional narrow understandings of transport and towards a social approach (Banister, 2008; Urry, 2008). Very often the main dimension of cycling mobility that policies tend to be concerned with is infrastructure. These are the policies in relation to planning and designing cycle tracks and lanes, speed management and road safety. Perhaps correspondingly, the most cited literature in the field of cycling research focuses road safety, infrastructure and the role of the environment on behavior (Dill, 2019). This is despite of one of the most cited papers in cycling research already making the point one decade ago that increases in cycling require packages of different, complementary interventions—being infrastructure just one of them (Pucher et al., 2010).

It could be useful to think about integrated cycling policies, those in which the multiple dimensions of cycling mobility are taken into account. These dimensions would of course include cycling infrastructure as characterized above, but also (based on Anaya-Boig, 2021):

- Regulations: law and regulations set the conditions in which cycling can take place. They are both part of the context and instruments of policy that can be approved, modified and enforced. In spite of the relevance of regulations, the academic production on this dimension limits to a few studies about road safety and vehicle-related standards.

- Training and coaching: cycling mobility skills need to be learned; these are knowledge transfer policies. They are often part of the suggestions in cycling infrastructure and behavior studies but have been very scarcely studied in the literature.
- Governance: the interactions between different actors within the practice of policy making determine the outcomes of such policies. Some authors make a difference between participation and the more empowering and fair interaction of democratic planning.
- Communication: relates to the way cycling mobility is communicated in policy making, the discourse: the representation of cyclists, the language with its conscious and unconscious meanings and the information communicated by any other signs. The words used to designate people who cycle or who drive, or the images featured in a policy document, create meaning in relation to cycling mobility.
- Social and cultural movements: eminently disregarded in policy, cycling cultures are an essential source of information in order to understand cycling mobility and be able to project it into the future through planning and policies. Social and cultural movements are diverse, complex, and contextual. The history of cycling mobility in a specific place (as described in the introduction to this chapter) or the social movements created around the practice of cycling (the critical mass, for example) would be part of this dimension.
- Planning instruments: this dimension compiles all the documents and manifestations of cycle planning or strategies. Some institutions produce specific cycling instruments, others include cycling within their mobility planning, for example Sustainable Urban Mobility Plans (SUMPs). But it is also important how cycling mobility is integrated in other thematic planning instruments related to energy, the environment, health, economy, tourism, and others.

Incomplete approaches to cycling policy by the institutions involved in policy making might be influenced by a techno-centric approach (based on technological solutionism), in which engineering is the top discipline and the rest have not often been invited to join the debate. Interdisciplinary work is thus a suggested way forward (Walta, 2018).

What are Cycling Policies For?

Cycling policies aim at making cycling accessible. It is preferable to use “accessibility” rather than “promotion” as the goal of cycling policies. The term “promotion” has been profusely used in relation to cycling policy, but it comes from the marketing field, and it is meant to persuade people to buy a product. In promotion, it is not so important who the “buyers” are and whether the benefits (and burdens) of the product are reaching all of them and in which way. But research shows that cycling is not available for everyone who could benefit from it; women, low-income populations, lower educated people, migrants, refugees, ethnic groups are under-represented amongst cyclists. A marketed product might not be available for people with different needs and in a variety of contexts—they just cannot buy it. There are assumptions made by the promoters of the product (cycling) that create exclusion. For example, sportive, white, middle class men, might promote vehicular cycling as an approach to cycling infrastructure (i.e., sharing the road with motorized vehicles in all situations and for everyone). Some transport planners tend to plan for “people like them” (Ralph and Delbosc, 2017). Research has shown, though, that women, elderly and other groups in the population do not feel safe enough to practice cycling mobility in that way and prefer protected infrastructure (Aldred and Dales, 2017). The lack of social and cultural diversity in decision-making teams involved in cycling policies may be creating noninclusive outcomes and cycling inequalities.

Aiming at “accessibility” allows cycling policies to be universal but targeted at the same time—the use of the terms such as universal and targeted are borrowed from current debates in health policy (Carey and Crammond, 2017; Marmot, 2020). “Universal” refers to the aim of making cycling accessible for everyone. “Targeted” cycling policies mean that individuals with different personal and contextual factors might require a different combination and level of provision of cycling policies in order to have access to cycling (also referred to as “proportional”). A universal approach in itself would only be egalitarian (the same for everyone) but adding a targeted element would integrate proportionality, hence providing a more equitable outcome. An example of the tensions between universal and targeted approaches in cycling mobility are illustrated by migrant people and refugees arriving in a new location. The financial situations of these population groups are very precarious, and they need to be mobile, especially for job-seeking and caring purposes, with the lowest possible cost. Let us imagine they arrive in The Netherlands, the best possible environment to cycle, where cycling is actually the default mobility option; but they have not learnt how to cycle. Cycling would be of great help economically and socially for migrants and refugees but the fact that there is infrastructure does not really help that much. They need specific training programs, taking into account their specific needs, to provide them with access to cycling mobility (Mohammadi, 2019; van der Kloof et al., 2014).

The question about the purpose of cycling policies at the beginning of this section is thus very much linked to another one: “Who are cycling policies for?”, and both can be connected through accessibility. Not everyone should cycle but everyone should have access to cycling, even more so those who might be able to cover basic needs and have better opportunities by doing it. Making cycling accessible for all means that the effects of cycling policies need to be fairly (not equally) distributed. As a result, distributive justice requires a wider understanding of accessibility than used traditionally in transport planning (Pereira, 2018). Accessibility consists in reaching places and opportunities from a given location; cycling accessibility entails being able to do it cycling for the whole trip or combining it with other suitable and affordable means, for example, public transport. Access to cycling is not only provided by the proximity to infrastructure and other facilities, but also it requires to be affordable, to have the skills to do it, information, an appropriate vehicle; that is to say it depends on personal, social, cultural, and environmental characteristics. Ideally,

cycling policies would aim at providing access to cycling through a variety of dimensions (as the ones listed above), so that the population would then be able to select and combine those that enable them to cycle in their personal and contextual situations.

How are Cycling Policies Made?

Policy making often activates after realizing there has been a change in the situation and there is a need to control it, to make it safe and secure and to regulate its terms and conditions. This might have been part of the process that happened historically when a technological innovation such as the bicycle was introduced, as described in the first section. In relation to cycling mobility, these changes have intensified over the past couple of decades with public bike-sharing schemes, e-bikes, private dockless bike-share schemes and the use of e-scooters for mobility all over the world—all of which have been grouped under the new term “micromobility.” After this kind of changes, it takes time to respond with new policies. However, radical changes or disruptions can accentuate the need for policies and thus create greater opportunities for faster implementation (Marsden et al., 2020).

In the year 2020, a major disruption caused by the SARS-CoV-2 global pandemic has deeply affected mobility, causing the immobility of a considerable part of the population with lockdowns and quarantines; and the mobility of essential workers, most of them being exposed to high risk of infection in their job places. As population started to show with their practices, the safest way to move in this situation was perceived to be the individual transport. Population demands called for a response from policy makers. Some of the response and recovery policies consisted of increasing the provision of space for cycling. In some places, funding has been made available for the construction of cycle lanes. In other places, dedicated space for cycling has been implemented in a “tactical urbanism” fashion, that is, low cost, provisional, and pop-up cycle lanes. This situation brings to light some specific issues in relation to the production of cycling policy; one is about the distribution of space and the other is about governance. Additionally, there are the ongoing challenges of translation, that is bridging cycling research and policy making.

Space is one of the key resources that mobility policies need to manage. Cycling happens in a specific surface, that can be dedicated to cycles or shared with pedestrians or with other vehicles. This is usually street space in which cycles can be used or parked. Street space is contested in many ways, revealing that there are power relations about the use of space. Space for mobility is unequally distributed, dramatically skewed toward automobility. Cars occupy the public space for parking and traveling in a very inefficient way, and automobility is responsible for a considerable fraction of air pollution, traffic deaths and injuries and other undesirable impacts. Cycling mobility policies necessarily deal with the use of space; how much space is there for cycling, how is this space, where is it located, how is it used, how is it regulated. Thus, cycling policies inescapably need to challenge automobility, which has accumulated a disproportionate amount of street space over the last 70–90 years. The negotiation of space for cycling is at the core of cycling policies, with the outcomes of this struggle often being very disappointing. Conscious or unconsciously biased arguments in favor of keeping space for automobility can distract negotiators from what the real stakes are: accessibility. Although access to cycling is not only achieved through space, space is necessary to access cycling mobility. With the pandemic crisis, a heavier and urgent argument in favor of cycling mobility creates a window of opportunity to shift the balance and reclaim space for cycling. Automobiles are also perceived as pandemic-safe individual transport mobility options although their negative impacts persist in this situation and risks related to air pollution have even increased. The tension between both is maintained as the pandemic continues.

Governance seeks to disperse the state power amongst all kinds of public, voluntary and private organizations with which the government interacts (Marsden and Reardon, 2018). In the negotiations described above, power relations are preventing a more equitable outcome, which could be understood as a governance failure. Literature shows concerns over the social equity and the contribution to sustainability of cycling governance processes framed as participatory and with the goal of “promoting” “smart” cycling policies (Gironés and Vrščaj, 2018; Nikolaeva et al., 2019). Some authors propose a shift toward the democratization of cycle policy and planning in which the power is more balanced and communities can be empowered and feel more ownership of cycling policies (Sagaris and Arora, 2017). Teams of policy makers and planners should be multidisciplinary and inclusive, welcome and combine multiple expertise and points of view in order to break the above-mentioned tendency to plan for “people like them” (Ralph and Delbosc, 2017).

There are different institutions involved in cycling policy making; governments and consultancies are in the frontline. Advocacy groups, lobbies and platforms, and civil society should be involved through the governance process. Consultancies are usually the main source of technical knowledge, they are commissioned and supervised by governments. But in places where cycling levels are low, cycling mobility technical knowledge and even research, is often placed in advocacy groups, as described in the example of the Copenhagen first cycling plan, which was drafted by the cyclists’ federation in the 1970s and unofficially implemented reluctantly by the city council during the 1980s (Oldenziel et al., 2016). The process of formalizing, legitimizing, and institutionalizing cycling mobility knowledge is at different stages in different countries. In contrast, places with a longer tradition in cycle planning, may have formal training programs and approved technical manuals based on scientific evidence. Over the last decades, there has been a process of knowledge transfer from cycling advocates who have turned into technical consultants, city officials and researchers. However, there is still a gap between the different kinds of institutions that is preventing the circulation of knowledge. Policy makers cannot access research for diverse reasons (research is behind paywalls, lack of information literacy, lack of time to read academic papers, unfamiliarity with the formats and language, etc.). Evidence-based technical manuals for policy makers are still scarce but very useful for the translation of the scientific evidence into infrastructure design (see e.g., Parkin, 2018). On the other hand, researchers still seem to be assuming that producing the evidence is enough to convince policymakers. There is a lack of mutual exploration, scientists do not explore how policy making works so that they produce appropriate evidence and outcomes and policy

makers do not approach research because they do not perceive research outcomes as useful or accessible for them. Government and academia need to find ways to collaborate and establish a dialogue so that the activities of both institutions are more aligned, and for them to find ways to communicate more effectively.

What Works?

One of the most frequent questions in cycling research is why people cycle. Studies have found that both objective and perceived built and social environments are important. That is to say, infrastructure is important but the perception of, for example, comfort is important as well. The same happens with road safety and social support; objective measures of both show their relevance in cycling behavior but so does the perception of them—which does not necessarily correlate with the objective measure—. It is also known that cyclists feel safer in protected infrastructure and in roads with reduced speed limits. Protected infrastructure is even more important for certain groups to feel safe when cycling, like women and elderly people. In summary, factors like social background, attitude towards cycling, travel distance, infrastructure quality, and bicycle practice have been found to be important (Walta, 2018). But these findings are from studies undertaken in specific places and what they found for those places is not necessarily applicable in other places. Furthermore, historical and cultural contexts are usually not taken into consideration in the majority of these studies (Cox and Bunte, 2018). Hence, it should be questioned to what extent these findings can be generalized.

The reality is that there are big differences in the uptake of cycling mobility in different countries and even between cities within the same country. There is a tendency to assume that whatever seems to support people cycling in a specific place, could potentially make people cycle in other places. Cycling is increasing globally, and some experts argue that this is because noncycling countries have “adopted” cycling policies from cycling countries (Pucher and Buehler, 2017). Whether adoption is an adequate term in these cases has not been proved; cities do not necessarily acknowledge where they have transferred their cycle policies from, and mechanisms behind the transferability of cycling policies have not been made explicit nor sufficiently studied yet. Even if policy makers in a city claim that they are implementing “Dutch-style” cycling policies (e.g., infrastructure designs), they will never look and work exactly in the same way as they did in the original location where they were observed—if they were actually observed in any way. Other authors suggest to lower the intensity of the relation with the original policies by using inspiration rather than pretending to copy (Vigar, 2017). Transferability can support the design and implementation of cycling policies, but is it possible to know enough about a specific cycling policy in order to transfer it successfully? Multiple questions arise in parallel; why is that specific policy selected to be transferred? how is success defined? In transferability it is common to use the term “best practice”, but the evaluation of the original policies can be shallow and politically manipulated (Macmillen and Stead, 2014; Vigar, 2017). One further question related to transferability is about how important is finding that inspiration outside rather than locally. Some authors actually suggest that the way forward in cycling policy transferability is to realize local potential (Walta, 2018), which seems to support the importance of taking into account nonexpert knowledge (Attard and Enoch, 2011; Vigar, 2017) through more democratic governance structures (Sagaris and Arora, 2017). Transferability has been practiced across all transport policies, but it seems that cycling policy making has higher hopes in it, probably due to the lack of knowledge of policy makers and practitioners in places where cycling levels are low.

Summary and Conclusions

Cycling policies vary across cities and countries, as levels of cycling mobility do. The importance of historical and cultural contexts to understand the levels of cycling mobility is under-estimated. The object of cycling policies, cycling mobilities, is often reduced to the infrastructural dimension, whereas there are other dimensions that need to be integrated such as regulations, training and coaching, governance, communication, social and cultural movements and planning instruments. In order for cycling to be inclusive, the goal of cycling policies needs to shift from sheer promotion to making cycling accessible for everyone. The universality of cycling policies combined with a targeted approach for specific population groups allows more equitable outcomes. Mobility disruptions that reinforce the advantages of cycling mobility create windows of opportunity for policy makers to break through political barriers and reclaim the space that has been taken over by automobility. Democratized governance practices and inclusive teams of policy makers could produce more equitable cycling policies. Siloed institutions block knowledge transfer; more collaboration between policy-makers, researchers and the civil society is needed to better understand cycling mobility, balance power relations and co-create fairer policies. It is assumed that cycling policies from the “cycling paradises”—places that have high levels of cycling mobility—can be transferred to increase cycling levels elsewhere. However, the mechanism of cycling policy transfer has not been studied accurately enough, but rather relies on assumptions and is manipulated with political interest. There might be excessive expectations placed in cycling policy transfer that can be strengthened through re-valuing local potential, connecting all sources of knowledge and leveling power relations in the governance structures.

What is Community Severance?

Community severance occurs when transport infrastructure or vehicles using that infrastructure are a physical or psychological barrier to the movement of pedestrians and other modes of local transport, separating people from places and from other people. This may lead to changes in travel behavior and to wider negative effects on individuals, including restricted access to goods, services, resources, and opportunities; higher probability of social exclusion; fewer social contacts; and impaired health and well-being (Anciaes et al., 2015; Hérán, 2011; James et al., 2005; Mindell and Karlsen, 2012; Mindell et al., 2017). It can also lead to effects at the level of the community, including reduced vitality of local businesses, reduced social cohesion, and deterioration in the local environment (Appleyard and Lintell, 1972; Appleyard et al., 1981; Appleyard, 2020; Jacobs, 1961).

The concept of community severance is sometimes described as the “barrier effect” of transport. Although the two concepts are often used interchangeably, barrier effect tends to refer mainly to the loss of mobility and accessibility of pedestrians, while community severance also includes the wider negative effects on individuals and communities (Anciaes, 2015).

Causes and Extent of the Problem

The most extreme cases of community severance are those posed by linear transport infrastructures (such as motorways, dual-carriageway roads, and railways) where longitudinal movement by pedestrians is not allowed and transversal movement is limited to a few locations where grade-separated pedestrian crossing facilities are provided (e.g., footbridges or underpasses). In this type of infrastructure, severance is enforced by embankments, cuttings, or physical barriers (e.g., walls, fences, guard railings) that prevent pedestrians from crossing (Fig. 1). Rivers and canals can also cause severance, although this is usually attenuated by the amenity value they provide.

Severance can also be caused by the vehicles using the infrastructure, even in cases where crossing is physically possible. This is the case of roads with large amounts of motorized traffic, or traffic moving at fast speed (Fig. 2). Pedestrians find it difficult to cross these roads outside designated crossing facilities due to the lack of safe gaps in the traffic. This is aggravated in roads with many lanes; complex road layouts (e.g., roundabouts, large junctions, turning lanes); many large vehicles in the traffic (e.g., buses, heavy goods vehicles); vehicles parked on the curbside; and lack of dropped curbs or a median strip where pedestrians can stop while crossing. Public transport vehicles running on dedicated lanes (including tram and light rail lines, and bus rapid transit systems) may also cause severance.

Crossing facilities often aggravate, rather than reduce, severance. Underpasses are prone to flooding and tend to be perceived as unpleasant and unsafe, especially when they have insufficient lighting or are poorly designed and maintained (Fig. 3). To a smaller degree, these issues also apply to footbridges, which can also be problematic for people with fear of heights (Fig. 4). Using underpasses or footbridges also implies extra effort and detours to use stairs or ramps. In some cases, ramps (or lifts) are not

Figure 1 Severance caused by transport infrastructure (Dubai, United Arab Emirates).

Figure 2 Severance caused by motorized traffic (Shanghai, China).

Figure 3 Severance aggravated by crossing facilities (underpasses) (Chişinău, Moldova).

Figure 4 Severance aggravated by crossing facilities (footbridges) (Valparaíso, Chile).

provided, limiting the use of the facilities by older people and those with mobility impairments. At-grade crossing facilities, such as signalized crossings, also have problems, when waiting time is long or the time allowed for crossing is too short.

Large nonlinear transport infrastructure, such as car parks, railway stations and depots, ports, and airports, may also pose barriers to pedestrians. However, movement across railway stations is sometimes possible—stations can even be one of the few safe crossing points to cross the railway line.

In some cases, severance caused by transport infrastructure is compounded by the presence of other land uses with poor permeability for pedestrians, such as industrial areas, hospitals, and university campuses. This may lead to the isolation of some residential areas, which become enclosed by barriers to pedestrian movement on all sides.

Severance can originate from a variety of processes. For example, a new transport infrastructure may be aligned to cross an existing community. This is often due to geographic and technical constraints, but it can also be due to economic factors (e.g., lower value of the land crossed) or political factors (e.g., lack of political power of local communities, or political bias of decision makers) (Appleyard, 2020). A different process leading to severance is a progressive change to an existing infrastructure, such as the increase of road traffic volumes resulting from urban and economic growth. This is often accommodated by planners with changes to the road design, such as widening the carriageway and reducing the number of pedestrian crossing facilities.

Severance can also originate from the emergence of new residential areas around transport infrastructure crossing previously nonresidential land. This often happens due to urban growth, as previously “undesirable” areas crossed by transport infrastructure become one of the few possibilities for new land developments. The desirability of those areas, translated into land values, may increase because the presence of transport infrastructure increases accessibility by motorized modes. Again, political factors are relevant, as the conversion from nonresidential to residential land depends on land use regulations.

The problem of severance is spread around the world, especially in urban and suburban areas (see, e.g., Future of London, 2018). While some solutions are being implemented in some cities, reviewed later in this chapter, severance is intensifying in others. In large and fast-growing Asian cities, the increase in travel demand has often translated into massive multilevel roads, where the barrier effect is compounded by visual intrusion (Badami, 2009). In many developing countries, growing investment in roads has also failed to address the needs of pedestrians, even where walking is still the main mode of transport (Bradbury, 2014).

Direct Effects

The main direct effects of community severance are the loss of mobility (ability to move) and accessibility (ability to reach places) of pedestrians. In the presence of a barrier, pedestrians must either make a detour to reach crossing facilities (which implies extra effort and delays to walking trips) or cross in a place without facilities (with the associated risk of collision with vehicles). In both cases, the barrier can also be perceived by pedestrians as unpleasant due to exposure to noise, vibration, dust, and air pollution; feelings of intimidation caused by vehicles; and personal security issues of using an environment dominated by motorized vehicles and with few other pedestrians (Hine 1996; James et al., 2005; Mindell et al., 2017). Although most of the existing evidence deals with pedestrians, some of these effects also apply to cyclists. Detours and delays also affect the provision of services such as bus routes, post distribution, freight, waste collection, policing, and emergency services, as well as local trips by private car.

Regardless of the effect on movement across the barrier, there is also a psychological effect of being separated from the other side. This can be explained by the visual intrusion of the infrastructure and auxiliary structures (e.g., walls, fences, noise barriers, crossing facilities) or the noise and air pollution from traffic (Héran, 2011). This psychological effect may change the residents’ perceptions about their local area. Qualitative studies have shown, for example, that when barriers exist, residents will have a narrower “personal

Figure 5 Chain of potential wider effects of community severance.

neighborhood," limited to their side of the barrier (Lassière, 1976). In addition, they will tend to have negative perceptions of the area next to the barrier on their side, and of the whole area on the other side.

However, the existence and extent of the direct effects of severance depend on how the barrier interacts with the local built environment. The separation of a residential area from another residential area or from a commercial or leisure area is more impactful than the separation from an industrial estate or undeveloped land. It is also likely that severance increases with proximity from the barrier, although not linearly, because people living next to the barrier may not dissociate the barrier effect from other effects, such as noise and air pollution. Feelings of severance may also extend far from the barrier, if the barrier disrupts the individuals' movement patterns. This is for example the case when difficult access to bus stops or a train station located on the other side of the barrier affects the frequency and destinations of non-local trips.

Feelings of severance also depend on perceptions about the barrier. The same traffic volumes and speeds are perceived differently by different people at different times of the day (Anciaes et al., 2017). Individuals who use the infrastructure for movement by car or public transport, or as destination for shopping, may not perceive the infrastructure as a barrier. Even underpasses and footbridges can become attractive when they have an innovative design or become shopping areas. Perceptions of severance may also decrease with the amount of time the individual has lived near the barrier. A new barrier disrupts existing mobility patterns and perceptions about neighborhoods but, with time, individuals may adapt to the barrier (Lassière, 1976). Finally, barriers can even be regarded positively if individuals wish to be separated from the communities on the other side.

Wider Effects

The direct effects of severance may lead to a complex chain of wider negative effects, mediated by changes in the behavior of individuals and organizations. These effects may be felt at the level of individuals or the whole community (i.e., residents, workers, and other people using the area). Fig. 5 synthesizes the chain of effects, which are described in detail the subsections below. It should be noted that although all the links in the figure are plausible, they are supported by varying levels of empirical evidence.

Behavior of Individuals and Organizations

The loss of mobility and accessibility due to the barrier is a constraint to the travel behavior of local residents. Individuals may change their routes to avoid the barrier, or change their destinations, going to places on their side of the barrier, rather than those on the other side (Anciaes et al., 2019; Hine 1996; Mindell et al., 2017). They may also reduce the number of trips or change travel mode, replacing walking and cycling with trips by motorized modes (car or bus), even when the destinations across the road are within

walking distance (Powers et al., 2019). The use of streets as social spaces is also likely to decrease (Appleyard and Lintell, 1972; Appleyard et al., 1981). In the longer term, severance may influence decisions such as whether to own a car and where to live.

Businesses and public organizations may also adapt to the presence of the barrier and to the changes in the individuals' travel behavior. Possible effects include more businesses catering to car users (in larger premises with car parks); and facilities being provided on both sides of the barrier, to cater to what have become separate markets. The routes of services such as post and waste removal may also change to reduce detours and delays. In the long term, the separation of communities may contribute to changes in school catchment areas and administrative areas.

Wider Effects on Individuals

The constraints that severance imposes on travel behavior reduce the individuals' ability to access goods and services, when the facilities providing them (e.g., shops and public facilities) are located on the other side of the barrier (James et al., 2005; Mindell et al., 2017). It also affects the ability to access opportunities such as employment, education, leisure, and other people. This may increase the probability of social exclusion and reduce the individuals' network of social contacts (Mackett and Thoreau, 2015).

Health and well-being can be affected through a variety of pathways. This can be a direct effect of the reduction in physical activity (via the suppression of walking trips), social exclusion, and reduction of social contacts; three pathways with solid evidence from public health research (see Mindell and Karlsen, 2012). Reduced accessibility also affects decisions to visit health-supportive destinations such as health centers, public parks, and shops offering healthy food. The stress and anxiety linked to collision risk, psychological effects of separation, and restrictions to access places and people may also affect mental health and subjective well-being.

Wider Effects on Communities

Local businesses are affected by the constraints posed by severance on the number of trips that local residents make and the travel mode they use. Evidence shows that although car users tend to spend more than pedestrians do on a single visit to shopping areas, they also make fewer trips, resulting in an overall negative effect on expenditure in local businesses (Jones et al., 2007). There is also a tendency for areas next to large transport barriers to have little economic activity due to low pedestrian flows (Jacobs, 1961). Severance is also linked to other negative economic outcomes, including income loss (due to constraints in accessing employment and education); depreciation of residential and commercial property prices; costs of extra trips by motorized modes; cost of detours to the routes of services; and congestion due to the increase in local traffic. In rural areas, there is also a loss of efficiency due to the separation of fields.

Social cohesion is also affected by the lower level of use of streets as social spaces; perceptions of separation and reduced social contacts within the community; and social exclusion of some individuals (Appleyard and Lintell, 1972; Appleyard et al., 1981). As noted, severance also influences perceptions of personal security and may even contribute to an increase in crime and vandalism, due to the reduction in the number of people using the streets and people's reduced sense of ownership and responsibility for their neighborhood.

Due to the replacement of walking trips with trips using motorized modes, severance also has environmental effects, both local (e.g., noise, air pollution) and global (e.g., use of nonrenewable resources, emissions of greenhouse gases). Outside urban areas, severance brought about by transport infrastructures and motorized traffic affects the movement of wildlife.

Equity Issues

Severance raises equity issues, linked to its effects on vulnerable groups. Due to collision risk and exposure to pollution on busy roads, adults will be unwilling to let children walk, cycle, or play outdoors unsupervised, affecting the children's independence and mental and physical development (Shaw et al., 2015). Due to their slower walking speeds, older people and those with mobility impairments are also vulnerable when crossing busy roads and may respond by suppressing walking trips (Musselwhite and Haddad, 2010). This restricts independent mobility and social contacts, two of the main components of healthy living for those groups. Older people, as well as women, also tend to be more concerned with personal security when using footbridges, underpasses, and roads dominated by vehicles and with few other pedestrians (James et al., 2005).

Some groups are also constrained in their actions to reduce severance due to the lack of alternative modes of transport, travel destinations, or walking routes. For example, low-income groups face more economic constraints to own and use a private car and may not be able to afford public transport. In most countries, women also tend to have lower levels of access to private vehicles and more demands on their time. In some cases, older people and some ethnic and religious groups are also dependent on local facilities and social contacts. Older people and those with impairments also find it more difficult to make detours to walking trips (Mindell et al., 2017).

Equity issues may also arise due to patterns in residence location of some groups. There is evidence that low-income groups tend to be disproportionately exposed to negative effects of transport such as noise and air pollution. This may be explained by the sorting of income groups to different levels of environmental quality, through housing markets: properties in cleaner and quieter areas have higher prices and rents, and may be unaffordable to low income groups. There is also some evidence of ethnic minorities being

disproportionately affected by noise and air pollution, which may be due to an income effect, segregation, or lack of political power of those groups. It is possible that these patterns also apply to severance, although empirical evidence has only recently started to emerge (Lara and Silva, 2019; Appleyard, 2020).

Policies

The most radical policy intervention to address severance is to remove the infrastructure causing the problem (Bocarejo et al., 2012). The most well-known example is the Cheonggye Expressway in Seoul, a multilevel motorway removed in 2005 to restore a stream and create a linear park. There is solid evidence of the success of this type of intervention, as shown by indicators such as increases in walking trips and in the use of public places, and increases in the value of properties in nearby areas (Kang and Cervero, 2009). However, when the removal of the infrastructure is accompanied by building a bypass in other areas, the problem is simply displaced. Even when bypasses are built in nonresidential areas, market processes may lead to the area becoming residential in the future, recreating severance. Rerouting the infrastructure to be aligned with a river or other natural feature also restricts access and reduces the amenity value of that feature.

Another option is to shift the infrastructure up or down. For example, the Central Artery in Boston was partly buried in a tunnel in 2003 and replaced with parks and a boulevard. This solution is expensive and not always technically feasible. A less expensive solution is sinking, without burying, the infrastructure, which allows for the replacement of grade-separated crossing facilities with at-grade facilities, although this still limits the number of available crossing points. Moving the infrastructure up, using flyovers, removes the barrier to pedestrian movement, but it does not remove, and can in fact increase, the psychological effect of separation, due to visual intrusion.

The barrier to pedestrian movement can also be reduced by adding new crossing facilities, which increase the number of available points where pedestrians can cross, reducing detours and increasing safety. Other options include modifying the type of existing facilities (e.g., replacing footbridges and underpasses with at-grade facilities), changing their location (to align with pedestrian desire lines), or changing their characteristics (e.g., improving the design and maintenance of footbridges and underpasses; and reducing crossing stages and allowing more time to cross in signalized crossings).

Another possibility is to make crossing easier at the points where no formal crossing facilities are provided. In the case of roads, this can be achieved by removing physical barriers; reducing the number of lanes assigned to motorized modes or the width per lane (reallocating the released space to pedestrians); or simply by adding dropped curbs and pedestrian refuges in the middle of the road. Adding a median strip extending along the road also allows pedestrians to walk along it and cross when a suitable gap in the traffic appears. "Courtesy crossings" have also become more common, using design features such as stripes, colored or textured surfaces, visual narrowing of the carriageway, and ramps, to encourage drivers to stop for pedestrians.

Severance can also be reduced by policies to change traffic, rather than the infrastructure. Road traffic volumes can be reduced by regulatory policies to restrict traffic (e.g., closure of roads to motorized traffic, road space rationing, one-way traffic schemes, high-occupancy lanes, removal of parking spaces) or by economic policies such as road pricing. Traffic speeds can be reduced by imposing lower speed limits, enforcing existing limits, or adding traffic calming design features. The problem of these interventions is that traffic volume and speed usually have an inverse relationship, so reducing one may increase the other.

Minor changes in the road environment can also reduce perceptions of severance in busy roads. Examples include improving pavements; removing obstructions; adding dropped curbs; and adding or improving lighting, greenery, street furniture, surveillance, and provision for the mobility-impaired. Even in the cases where crossing is not possible, improving the environment at the places where the local street network meets the road may also improve negative perceptions about the barrier.

Despite their potential benefits, it is not easy to make a political or business case for interventions to remove or reduce severance. This is partly because there are few established methods to objectively identify severance, measure its intensity, and assess the effect of interventions to reduce it (Anciaes et al., 2015). National-level official manuals for the assessment of transport projects often omit severance or mention it in a checklist of social or environmental impacts, without providing practical guidance. In some cases, simple qualitative scales are proposed, with a few loosely defined points. At the city level, only a few governments use quantitative indicators. For example, Transport for London uses a weighted average of number of lanes, traffic counts, and speeds. Methods for the monetization of severance are even rarer and when they exist, they capture only specific aspects of the problem (Anciaes et al., 2015). For example, the official guidance in Germany, Italy, and Australia currently suggests monetizing detours to walking trips by applying unit values of time. The tendency has been for less, rather than more, objectivity in the assessment of severance and in several countries (Sweden, Denmark, Switzerland) detailed methods to quantify and value severance have been dropped from official manuals over the years.

Research

There is a long, if discontinuous, history of research on community severance; the earliest studies dating from the 1950s. Appleyard and Lintell (1972) conducted the first high-impact study, producing a simple but powerful result that people living in roads with higher levels of motorized traffic in San Francisco had fewer friends and acquaintances and made fewer trips across the road, compared to those living in quieter roads. During the late 1970s and early 1980s, there were parallel efforts in several countries, with

governments commissioning comprehensive reports on severance. A study for the Department of Environment in the United Kingdom (Lassière 1976) documented the impact of busy roads on the travel behavior and neighborhood perceptions of local residents. In France, Loir and Icher (1983) looked at the interaction between different types of road infrastructure, urban dynamics, and people's perceptions in creating severance. In Sweden, Korner (1979) systematized the various effects of road barriers into different levels and in Norway, Lervåg (1984) reviewed methods to assess severance.

In the following 25 years, the only studies dealing specifically with severance were a few methodological reports for transport authorities in England (Clark et al., 1991) and New Zealand (Read and Cramphorn, 2001; Tate 1997). Research resumed only in the 2010s, with a new emphasis on interdisciplinarity. In the United Kingdom, the Street Mobility project at UCL (University College London) developed a suite of tools to identify and measure severance caused by busy roads (Mindell et al., 2017). In France, Frédéric Héran published the first book-length study on severance (Héran, 2011), proposing a broad approach to study the problem, integrating it with other transport and urban issues. Evidence on the direct and wider effects of severance has also been growing, with studies replicating Appleyard and Lintell's results in several countries (Hart and Parkhurst, 2011; Wiki et al., 2018). Evidence has also emerged on the impacts of severance on subjective well-being (Anciaes et al., 2019; Foley et al., 2017).

Several assessment methods have been proposed but have seldom been included in routine transport practice. Some of the methods rely on simple indicators of the size of the barrier, obtained by quantifying characteristics of road design (e.g., road width, number of lanes) and traffic (e.g., traffic volumes, proportion of large vehicles, traffic speed). More complex indicators measure the effects of the barrier, such as delays and detours. These indicators are sometimes fed into broader indicators of accessibility to local facilities or catchment areas for walking trips (Van Eldijk, 2019). Unit values are usually multiplied by the size of the affected population, defined as the population living within a certain radius from the barrier. A few authors have proposed indicators based on pedestrians' perceptions of safety (Tate, 1997) and observed road crossing behavior (Russell and Hine, 1996). Surveys and qualitative methods (e.g., participatory mapping) have also been used to capture the perceptions and priorities of local residents (Mindell et al., 2017).

There have been recent developments in methods to monetize the benefits of reducing severance. These methods apply standard approaches for the valuation of nonmarket goods, based on willingness to pay. Stated preference approaches (e.g., Anciaes and Jones, 2020) use surveys capturing people's choices among different scenarios, which allows for the calculation of unit values for the characteristics of road design, traffic, and crossing facilities. Revealed preference approaches (e.g., Kang and Cervero, 2009) estimate the value of severance as reflected in market prices, usually property prices. However, in most cases, revealed preference approaches have treated severance as a yes/no issue (the presence/absence of the road) or in terms of a single characteristic (usually traffic volumes). A problem common to both stated and revealed preference approaches is that they cannot capture the overall cost of severance, especially the costs of the wider effects on individuals and communities.

Despite these developments, research on severance still lags that of other negative effects of transport, such as noise and air pollution, and is still faced with unanswered questions and the lack of robust assessment methods. Research has focused almost exclusively on the effects of road traffic on pedestrians in roads without physical barriers. Little is known about more absolute types of barriers, such as those posed by motorways and by railways, where severance derives mainly from the infrastructure itself, and not from traffic. Research has also not moved beyond the study of "barrier" to that of "enclosure," in areas that are surrounded by barriers on all sides. There is also little knowledge on the effects of severance on cyclists and local motorized traffic. Another important gap, which is becoming a pressing policy issue, is how to address severance in fast-growing in cities in developing countries.

Conclusions

Community severance, or the barrier effect of transport infrastructure and traffic, reduces the mobility and accessibility of pedestrians and users of other modes of local transport, and can lead to changes to travel behavior and to wider negative effects on individuals and communities. The problem is more impactful for children, older people, women, and low-income groups. There are several possible solutions to remove or reduce community severance but few methods for assessing those solutions. Research on severance still lags that of other negative effects of transport, such as noise and air pollution, and available evidence does not yet cover all possible transport barriers and their effects.

Introduction

Why Bus Priority?

Well-functioning travel and transport in metropolitan regions is one of society's strategic challenges. Public transport is essential for more sustainable cities because it contributes to efficient use of road space, reduces emissions, and plays an important role in social sustainability. Most urban public transport in cities across the world is road based (Currie, 2016), and the vast majority of buses operate on streets in mixed traffic (Vuchic, 2007).

In mixed traffic, the service speed and reliability depend on traffic conditions. Because buses also need to stop to pick up and drop off passengers, the average speed of the bus services is inevitably lower than the average speed of cars on the same route. Consequently, buses in mixed traffic are in general not very competitive with car travel regarding speed and reliability (Vuchic, 2007). In order to improve the situation, there are several possible measures that prioritize on-road public transport services over other road users. The umbrella term for these measures is *transit priority measures* or, specifically for buses, *bus priority measures*.

The benefits of bus priority can be divided into primary and secondary benefits (Currie, 2016). Primary benefits include passenger travel time savings and increased reliability in the form of improved punctuality or regularity (TCRP, 2013). Secondary benefits stem from the travel time and reliability improvements, and these occur at increasing scales as the primary benefits of bus priority increase (Currie, 2016). One such secondary benefit is fleet and operating cost savings due to more efficient vehicle and personnel cycles. Alternatively, the increase in timetable efficiency can be used for increasing the frequency of service without increasing costs.

Frequency, travel time, and reliability are quality attributes that are of particular importance for customer satisfaction and for the loyalty of public transport passengers as well as for achieving a modal shift in favor of public transport (dell'Olio et al., 2018; Hansson et al., 2019; van Lierop et al., 2018). Thus, modal shift is another secondary benefit of bus priority. After a certain threshold, land use benefits may also be obtained because the capacity of buses well exceeds that of cars. For instance, by replacing a mixed traffic lane with a bus lane the total transport capacity can increase without increasing the road space (Litman, 2016). Finally, bus priority might also be associated with considerable road safety benefits (Goh et al., 2014).

As a result, approaches to justifying bus priority based only on travel time impacts are too simplistic. All primary and secondary benefits need to be considered, as should cost and benefit trade-offs for all road users (Currie, 2016).

Types of Priority Measures

Bus priority measures can be divided into two main categories, namely priority in space and priority in time (Reynolds et al., 2017). The priority in space category includes measures prioritizing buses in the road space, for example, bus lanes, bus gates, and measures related to bus stops. Since the introduction of the first bus lane in Chicago in the late 1930s, various priority in space measures have proliferated throughout the world (Dadashzadeh and Ergun, 2018). The priority in time category is focused on intersections and

Figure 1 Bus lanes can be an efficient use of road space. In this picture there are approximately twice as many passengers in the bus as there are people in the cars occupying the other two lanes of the road. Photo: Västtrafik/Stina Olsson.

Figure 2 Categories of bus priority measures.

includes bus priority at traffic signals as well as priority for bus movements in unsignalized intersections. Sometimes other concepts are used, for instance, infrastructure strategies and traffic control strategies (TCRP, 2016), road design measures and traffic signal priority measures (Currie, 2016), or facility design-based measures and signal control-based measures (Diakaki et al., 2015). It should be noted that there is a slight difference in the two latter categorizations compared to the priority in space and time categories, and “traffic signal priority measures” and “signal control-based measures” exclude priority measures at unsignalized intersections. Early examples of priority in time measures relying on traffic signal control were implemented in European cities in the 1970s. In line with technological advances, more sophisticated variants of such measures have been developed and disseminated and are now commonplace in many cities around the world (Dinopoulou et al., 2013).

Based on the priority in time and priority in space categories, an example of how bus priority measures can be further arranged in subcategories is shown in Fig. 2. Each of these subcategories in turn contains a variety of priority measures (Currie, 2016; Dadashzadeh and Ergun, 2018; Diakaki et al., 2015; TCRP, 2016; Vuchic, 2007).

For *bus stop design*, the best options in terms of bus priority allow buses to stop directly in the travel lane, thereby also avoiding lane shifts while braking or accelerating. One such option is the bus bulb, a curb extension typically replacing a roadway that would otherwise be part of a parking lane (NACTO, 2016). Bus stop lengthening can also be seen as a priority measure, allowing the bus stop to serve more buses simultaneously and hence avoiding buses queuing to enter the stop.

In Fig. 2, bus lanes are separated in two categories—short bus lanes near intersections and bus lanes along (longer) road segments. *Short bus lanes near intersections* are designed either to avoid queues ahead of the intersections—through queue jump lanes, bypass lanes, or freeway access ramps—or to enable buses to pass through the intersection using exclusive infrastructure—for example, bus gates or right-turn lanes. To also improve speed and reliability between intersections, *bus lanes along road segments* are

important. A number of options regarding design and operations are available and are suitable for different situations as well as for determining the level of separation from other traffic. For instance, curbside bus lanes are usually slower than median bus lanes or fully segregated busways (Vuchic, 2007). The level of priority is also influenced by the separation method such as line markings, colored pavement, or physical barriers. Furthermore, there are operational aspects to take into account, most importantly if the bus lanes should be reserved for buses only or if other vehicle classes should be permitted in the bus lanes, including taxis, bicycles, high-occupancy vehicles, or trucks. The vehicle classes are ordered according to their typical impacts on bus services, and taxis generally have less impact and trucks generally have more impact than other vehicle classes (Vuchic, 2007).

In the priority in time category, measures are focused on intersections. In this category, *unsignalized bus priority* is a simple but effective type of priority measure, meaning that streets with bus services are prioritized and crossing streets have yield or stop signs. This type of priority measure also includes turn restrictions so that turning movements in general traffic that cause delays for buses are prohibited. The movement restrictions may be complemented with exemptions for buses so that buses are allowed to make movements that are prohibited for other vehicles. Turn restrictions and turn restriction exemptions are here categorized as unsignalized priority measures, but they are also possible to implement at signalized intersections.

Presignals are signals before an intersection, where the intersection itself may be signalized or unsignalized. Presignals are a support strategy for bus lanes that end before an intersection. The presignals allow buses to reach the intersection ahead of other traffic even though the bus lane is discontinued (TCRP, 2016).

In signalized intersections, there is a multitude of possible strategies for implementing *traffic signal priority* for buses. These strategies can be divided into passive and active priority measures. Passive signal priority (also called fixed-time or off-line signal priority) means that expected bus movements are considered when designing the signaling system, for example, by weighting the proportion of green time given to a phase that is used by buses. Real-time conditions of the bus operations are not considered in passive signal priority strategies. With active signal priority (also called real-time or traffic-responsive signal priority), buses are detected ahead of the intersection, triggering signal phase adjustments that favor the buses. Examples of such adjustments are green extension, early green, stage skipping, and stage reordering. Active signal priority can be conditional, taking into account the operational status of the bus and whether it is delayed, on time, or ahead of schedule. In contrast, unconditional strategies provide priority regardless of the status of the approaching bus. Furthermore, active signal priority can be reactive or proactive. Reactive strategies are typically applied at each intersection separately, whereas proactive strategies use model predictions to plan for arriving buses when they are one or more signals upstream (Diakaki et al., 2015).

Measures concerning bus operations, aimed at improved travel times and reliability, are also mentioned in connection with bus priority measures, including, for example, bus stop consolidation, route design, and fare payment changes (TCRP, 2016).

In both the priority in space and priority in time categories, the available types of measures can be designed in numerous ways resulting in various levels of bus priority. This is particularly valid for the broad concept of traffic signal priority, which has a large set of parameters and a wide variety of options. The different levels of bus priority in these options are possibly associated with different levels of implementation challenges; the higher the level of bus priority, the more challenging it is to implement. Bus lanes, for instance, are a narrower concept with fewer opportunities for compromise in terms of the level of priority. Typically, the greatest benefits of bus lanes are obtained where competition for space is the greatest and where they are the most difficult to implement.

What are the Obstacles to Bus Priority?

As both Reynolds et al. (2017) and Singerman Ray (2019) point out, there is surprisingly little research on the implementation of bus priority measures. Because bus priority is a central aspect in the planning and implementing of Bus Rapid Transit (BRT), the majority of literature that exists about the process of implementing priority measures is focused on such large scale and often programmatic types of investments. Additionally, the data used in these studies are usually collected in case studies situated in the Global South, for example in Latin America, Asia, and Africa (Lindau et al., 2014; Muñoz and Geschwinder, 2008; Munoz and Paget-Seekins, 2016; Nikitas and Karlsson, 2015; Poku-Boansi and Marsden, 2018).

Literature that describes conditions for the implementation of bus priority measures in other contexts, and where measures are not part of an upgrading to BRT standard, is more limited. Pettersson and Sørensen (2019), who studied the implementation of bus priority measures in “conventional” bus services in Scandinavian cities, concluded that there were both similarities and differences when comparing their results to the BRT literature. A key difference is that large-scale BRT projects often have strategic ambitions, for example relating strategic urban development objectives or ambitions to reform the public transport sector (Muñoz and Geschwinder, 2008; Munoz and Paget-Seekins, 2016; Poku-Boansi and Marsden, 2018). In such policy contexts bus priority measures are parts of high profile, often politically charged policy packages with far-reaching objectives extending beyond the limits of transport system effects. In contrast, Pettersson and Sørensen (2019) and Singerman Ray (2019) highlight the incremental and day-to-day character of implementing bus priority measures in conventional bus services. Here, the endeavors are initiated and carried out mostly by public administration officers.

Conflicts Over Space

Regardless of context and whether part of a BRT package or not, it is clear that the implementation of bus priority measures is difficult per se and is often fraught with conflict. A key conflict concerns the redistribution of space between various road users, which

becomes particularly evident concerning measures categorized as priority in space in the introduction above. Previous research on bus priority measures in a BRT context, for example, Nikitas and Karlsson (2015) and Munoz and Paget-Seekins (2016), often emphasize the conflict involved in reallocating road space from motorists to bus passengers. Removing on-street parking spaces and loading zones to create space for bus lanes is also controversial (Singerman Ray, 2019). Pettersson and Sørensen (2019) also found that the conflict over road space involves other road users than motorists, such as cyclists and pedestrians. Generally, in any city that aims to increase cycling and walking, conflicts between priority measures for buses and measures to increase cycling and walking are likely to occur. Apart from having to address the issue of road space allocation, the conflict between bus priority and nonmotorized transport modes is also about clashing objectives where ambitions to increase the operational speed of buses can be difficult to combine with ambitions to improve traffic safety (Pettersson and Sørensen, 2019).

A second, related conflict is that it can be difficult to speed up bus service while simultaneously facilitating urban development and protecting “urban qualities”. People living in areas served by buses may not consider faster buses as something positive, but rather as a threat to their quality of life. Concerns about increased noise and inadequate road safety along thoroughfares, as well as the elimination of stops, are issues that have engaged the public and impeded the implementation of priority measures. If large-scale infrastructure measures are needed to ensure high and consistent speed for buses, there is also a potential conflict where high value of exploitable land in the cities impedes the implementation of bus priority measures that require a lot of space (Pettersson and Sørensen, 2019).

Institutional Complexities

With the term institutions, we refer to the institutional framework for the formulation and implementation of priority measures. This includes the organizational structure for public transport and the funding structure for bus services. It also includes the division of labor between different public authorities and the formal administrative processes within which planning and implementation of priority measures take place. Furthermore, institutions also include the values and norms of the persons working in different organizations responsible for different aspects of implementing priority measures (March and Olsen, 1989; Rye et al., 2018).

In general, the planning and implementing of bus priority measures can be impeded by institutional complexities. Complexity can, for example, concern ambiguities about which organizations have the formal mandate, and hence the budgetary responsibility, for various measures (Muñoz and Geschwinder, 2008). This, in turn, can result in institutional inertia, that is that it takes (too) long to make the necessary decisions in all the agencies involved or that measures are not implemented at all (Pettersson and Sørensen, 2019; Wright and Hook, 2007).

Thus, an important dimension of institutional complexity in relation to bus priority is linked to funding structures, both for public transport in general and for priority measures per se. As mentioned in the introduction of the chapter, bus priority measures can reduce operating costs. Alternatively, the efficiency gains can be used to increase the frequency of service without increasing costs. However, the funding structure of public transport influences the possibility to recoup the benefits of investments in terms of improved operating economy and more passengers. For many types of priority measures, the costs for implementation are allocated to an organization acting as the infrastructure holder, while the benefits accrue to the organization operating the service. This means that unless there are direct links between the budgets of the infrastructure holder and the operator there will be no direct economic incentives to invest in bus priority (Pettersson and Sørensen, 2019).

The norms and values of officials working in different organizations are also a source of complexity because they can have different views of the problem, and hence divergent views about which types of solutions are justified. One example of how this can impede bus priority is if mobility is measured as flows of vehicles instead of flows of people (Lindau et al., 2014). In a context of congestion, emphasis is often on improving the level of service based on flows of vehicles rather than people, and this way of viewing the problem could hamper the implementation of both priority in space and priority in time measures. As mentioned in the discussion of conflicts about space, officials who work with public transport and those who work primarily with other means of transport, such as cycling, car travel, walking, or more general urban development, often have conflicting views (Pettersson and Sørensen, 2019).

How to Manage Bus Priority Planning?

It appears from the above that implementing bus priority measures is not an easy task, and it is entrenched with difficulties and obstacles. Here we will turn to four “tools” that appear relevant when aiming to introduce bus priority in cities.

Acceptance

Conflicts over space and institutional complexity imply that leadership becomes particularly important, and it is often seen as a key factor for resolving conflicts and gaining consensus (Lindau et al., 2014; Muñoz and Geschwinder, 2008; Munoz and Paget-Seekins, 2016; Singerman Ray, 2019; Wright and Hook, 2007). However, leadership can take many different forms. In the paradigmatic cases of introducing bus priority connected to BRT in the Latin American cities of Curitiba and Bogotá, it was the mayors with great visions of how to transform the city who were the political champions representing the necessary leadership. In studies of the implementation of bus priority measures in Scandinavia (Pettersson and Sørensen, 2019) and the US (Singerman

Ray, 2019), political champions play a less prominent role. When bus priority measures are implemented as small, incremental changes to the existing system, the role of champions within specific agencies seems more important. In such cases political leadership is still important, but in a more reactive manner, for example, by providing support for implementation once it is shown that priority measures are actually working (Singerman Ray, 2019). This highlights that politicians are dependent on the population they represent. Lack of public support for bus priority usually implies that the political leadership is not experienced. This makes it important to involve the public in the processes of planning, designing, and implementing bus priority measures (Pettersson and Sørensen, 2019).

Collaboration

Due to the institutional complexity in implementing bus priority measures, extensive collaboration among many stakeholders is needed for such measures to succeed. This collaboration can be within and among different municipal, state, and regional authorities as well as bus operating companies and other public transport authorities or private operators. Establishing some degree of consensus, coordination, and common understanding among a wide variety of actors is central, and the presentation of a united front of politicians and officials has also been suggested to be important to be able to “sell” the project to the public (Finn et al., 2011).

Through experiences on collaboration in public transport projects in Scandinavia, a number of lessons for successful collaboration have been recognized (Pettersson and Hrelja, 2018). Establishing a shared understanding of the purpose of the collaboration and building enduring relationships seem to be of utmost importance.

Funding Models

While institutional complexity prevails and constitutes an obstacle when planning and implementing bus priority measures, some institutional set-ups are more conducive than others to the establishment of bus priority measures, and funding models seem to be one institutional feature of significant importance.

The funding structures of public transport as well as bus priority measures differ across the world. Often, the local public authorities are responsible for and fund the local road network, and in many cases local or regional public authorities also subsidize the provision of public transport. In such cases, the funding scheme for public bus transport can be set up to incentivize the local authorities to invest in bus priority measures. This is the case, for example, if the local authority fully or partly pays the costs of the provided bus hours after ticket revenues are considered. In that case, implementation of bus priority measures making the bus service faster and more attractive will make it possible for a local authority to reduce bus hours while at the same time increasing ticket revenue from more passengers. Thus, local authorities can recoup the investments in bus priority measures and can establish positive business cases (Pettersson and Sørensen, 2019; Singerman Ray, 2019). In addition, external funding sources, such as state or regional-level support of investments in bus priority measures, can also constitute an important incentive for local authorities (Pettersson and Sørensen, 2019).

Guidelines and Action Plans

Guidelines for bus priority as well as local action plans for the implementation of bus priority measures can constitute another important tool for planning and implementing bus priority measures, and a number of guidelines and toolboxes for introducing bus priority measures already exist. Some of these have been developed in connection to BRT (Finn et al., 2011; The Swedish Knowledge Centre for Public Transport, 2016; Wright and Hook, 2007), while others have been developed in other national or local contexts (e.g., National Capital Region Transportation Planning Board, 2011; TRCP, 2013, 2016).

While guidelines mostly contribute with planning and technical recommendations, action plans can represent the political commitment to introduce or further develop bus priority initiatives. Many cities are working with such action plans, e.g. Greater Wellington in New Zealand (Greater Wellington, 2019), New York City in the US (New York City, 2019), and Stockholm in Sweden (ÅF Infrastructure, 2016). To take Stockholm as an example, the capital of Sweden has a mobility strategy including goals to increase the average speed on the trunk bus lines, and together with Region Stockholm the city has developed an action plan identifying measures that can be implemented in the short term (Pettersson and Sørensen, 2019; ÅF Infrastructure, 2016). Action plans can constitute an important arena for collaboration between different stakeholders involved in implementing bus priority measures.

Concluding Remarks

Although technical guidelines are important tools in the implementation of bus priority measures, such measures are first and foremost a political issue. Implementation of bus priority measures is fraught with conflicts between different societal goals and interests, and solutions always imply a redistribution of mobility options among different groups of the population. Some will gain and others will lose. The barriers for implementing bus priority measures are founded in conflicts between different road user groups, and political leadership is essential for managing the implementation barriers. Across countries and continents, processes of policy making and the execution of political leadership differ. There are, for example, huge differences between political leadership in Latin America and such leadership in Scandinavia, and thus direct transfer of bus priority policies from one context to another is

not advisable. Rather, each city must translate and adjust appropriate ideas for implementation of bus priority measures to the city's specific context.

Biography

Claus Hedegaard Sørensen is a research leader at the Swedish Knowledge Centre for Public Transport (K2) and senior researcher at the Swedish National Road and Transport Research Institute (VTI). Claus is doing research on transport governance, and his research mostly focuses on environmental policy integration in transport, national transport planning, organization and collaboration within public transport, and the use and role of knowledge in transport policymaking. For the last couple of years he has researched and published mostly on governance of smart mobility. Thus, he has led and been involved in more research projects within that field.

Fredrik Pettersson is an associate senior lecturer at the Department of Transport and Roads, Lund University, and is involved in the Swedish Knowledge Centre for Public Transport (K2). His research interest is in the dynamics between different levels of decision-making and different organizations in the transition to a more sustainable transport system. In the last decade he has published research on national-level transport policy-making as well as planning and decision-making processes at the local and regional level.

Joel Hansson is a PhD student at Lund University and K2 – the Swedish knowledge centre for public transport. His PhD project aims at developing knowledge about effective and attractive regional public transport. Joel is the main author of the Swedish guidelines for Regional BRT. Before starting his PhD studies, Joel was a consultant, working with public transport strategies and analyses in Sweden.

Introduction

High-speed rail (HSR) is characterized by high speed. But what is high speed? The International Union of Railways (UIC) defines HSR as trains running on services with a commercial speed of at least 250 km/h. However, according to European directive 96/48/EC, in some specific cases, speeds above 200 km/h can be considered high speed, if this speed is a significant improvement upon the previous rail service. Across the world, HSR speed has evolved. The commercial speed of the first Shinkansen did not exceed 218 km/h. The commercial speed of the first French *train à grande vitesse* (TGV) in 1981 was 260 km/h, while the commercial speed of the newest TGV in France can reach 350 km/h; the maximum commercial speed of the ETR 1000 train, which runs in Italy, is 360 km/h, while the Maglev (which uses a different technology to all others) between Pudong Airport and the Longyang Road in Shanghai has been running at 430 km/h since 2002.

HSR developed during the second half of the 20th century, first in Japan with the Shinkansen (or bullet train) between Tokyo and Osaka. This was introduced in time for the 1964 Tokyo Olympics. HSR subsequently expanded to European countries: in Italy with the Direttissima, which partially opened in 1978 between Rome and Florence; in France in 1981 with the TGV between Paris and Lyon; and in Germany in 1988, Spain in 1992, Belgium in 1997, the United Kingdom in 2003, and the Netherlands in 2009. Outside Europe, it was developed in China in 2003, South Korea in 2004 and Taiwan in 2007.

The year 2003 was a crucial date for HSR, as it marked its arrival in developing countries, with the first line from Qinhuangdao to Shenyang in China. A few years later, in 2009, HSR reached Turkey, with a first line between Ankara and Eskişehir. The last developing country to launch HSR was Morocco in 2018, with the line between Tangier and Kenitra (Delaplace, 2018).

The Extension of HSR Throughout the World

As of October 2019, there were 47,560 km of high-speed lines (HSLs) in the world, with a further 12,892 km under construction. More than 40,000 km of lines are planned worldwide for completion by 2050 (UIC, 2019). It must not be forgotten, though, that HSR is a heterogeneous category in terms of technology and network types.

In terms of rolling stock, high-speed trains are characterized by new, powerful engines, new and improved train stability systems, different train lengths, and sometimes new facilities for passengers. HSR technologies have had to be improved in order to maintain stability at high speed, enable trains to stop safely, and minimize noise and vibrations near the lines (Givoni, 2006). A high-speed train is not a radical innovation in itself, although technologies may differ from one country to another. This is typically because they have been developed at different times, within the context of specific technological trajectories. Some HSRs, such as the Shinkansen or the French TGV use the same technology as older trains—that is, wheels that run on rails; others, such as Maglev, which make use of magnetic levitation technology, are more innovative because the train has no direct physical contact with the rail, thus eliminating friction and enabling speeds of up to 600 km/h. In Italy, the Pendolino is characterized by a specific mechanism that allows it to tilt on bends. In some European countries, however, the gauge is different, causing interoperability issues. In certain countries several technologies coexist.

High-speed trains must also be analyzed in conjunction with the type of infrastructure on which they run, which also varies by country. Campos and de Rus (2009) defined four different types of systems: first, an exclusive exploitation model with specific and separate infrastructures for high-speed trains and conventional services respectively, as in Japan. The second kind of system is the French model, characterized by high-speed trains which can run on either specific new infrastructure or conventional lines, which are sometimes upgraded. The third type is the Spanish model, where HSLs are also used by conventional trains. The fourth and final model is characterized by high-speed and conventional services that run on both types of infrastructure, as is the case in Germany and Italy.

Moreover, the locations of stations differ depending on the countries and cities in question. In China where there is fast-growing and extensive urbanization, HSR has been a tool for creating new intermediate cities between major cities (Yin et al., 2015), with the station acting as the point of departure for the city's development. In France, as in Spain, HSR sometimes serves central stations and in other cases serves new peripheral stations located directly on the high-speed line. In France, however, some HSR services call at both types of station.

Lastly, the network structure of HSLs can also be quite different, and depends on the urban structure of the country concerned. In some cases, the network is centered on a very large city, sometimes the capital, as in the case of Paris (although some intersector HSLs do allow trains to bypass Paris) in France, Madrid in Spain, Seoul in South Korea, and Tokyo in Japan; in other cases, there are HSR hubs in many cities, as in Germany and China.

Whatever the technology and the network configuration, HSR is mainly used for passenger transport (albeit with different aims (commuting, business, tourism, etc.) and not for freight, although some countries did formerly use HSR for postal freight services, as in France up until 2014 (Strale, 2016). Since November 2018, HSR freight services have been running overnight in Italy between the Maddaloni–Marcianise rail freight terminal (Caserta province, north of Naples) and the Bologna Interport (See: <https://www.rail-freight.com/railfreight/2018/11/02/high-speed-freight-train-italy-hits-the-track-on-7-november/?gdpr=accept>). Other freight projects such as Euro Carex in Europe and a project initiated by the China Railway Rolling Stock Corporation (CCRC), China's leading train manufacturer (This project was part of China's Medium- and Long-Term Railway Plan (MLTRP)), have also been under discussion for a long time.

While HSR technology is not a radical technological innovation, the effects of this technology on local dynamism, also referred to as the wider economic impact of HSR, has been at the core of numerous debates.

HSR and the City: The Issue of the Wider Economic Impacts

In cities that benefit from it, HSR can be seen as an “improvement innovation” that is expected to increase accessibility to the city. This undoubtedly attracts businesses and/or tourists. In many cases, HSR is also a tool for urban development projects.

HSR and Improving Cities' Accessibility

A new high-speed infrastructure can improve the accessibility of cities as a result of higher speeds and the induced reduction of travel times. As such HSR in Europe, for example, has modified the map of European accessibility. It has brought peripheral regions closer to central areas, but has also increased the imbalances between the main cities and their hinterlands. Vickerman (2015) considers the benefits linked to improved accessibility and connectivity mainly concern large metropolitan areas. HSR strengthens the regional and national roles of cities served by HSR, speeding up the processes of concentration and metropolitanization (Urena et al., 2009). Monzon et al. (2013) show that extensions of HSR to peri-urban areas in Spain have increased spatial imbalances and contributed to a more polarized spatial development, as HSR extensions are only built taking into consideration network efficiency. Conversely, when HSR lines are implemented in order to serve regions homogeneously, it has a positive effect on spatial equity (Monzon et al., 2013).

HSL improves the daily accessibility. As a result, an increase in commuter traffic may occur owing to modal shift, with weekly travel replaced by daily travel, especially for high-income passengers (Klein, 2003). But HSR effects on accessibility are unequal. It is evident that the effects of HSR on accessibility are linked to the resulting speed improvements, which vary across countries and cities. These speed improvements depend on the technical characteristics of the HSTs and of HSR infrastructures (Campos and de Rus, 2009), and the physical and human geographical characteristics of the land through which the train runs. For example, commercial speed may be limited in urban environments, or in areas with tunnels or bridges. Moreover, some HSTs also run on conventional rail lines at lower speeds. Many a times they depend on the previous rail service speed (Garmendia et al., 2008). If the speed of the previous conventional rail service was especially low, the speed improvements linked to HSTs will appear more significant.

Accessibility improvements also depend on:

- The quality of the new service in terms of frequency (which is correlated to the size of the city, the number and type of destinations, whether it reduces or eliminates the need for transport connections, whether it enables return journeys within the same day, etc. (Delaplace, 2017); the type of HST service (international or interregional) (Willigers and Van Wee, 2011).
- The location of HSR stations. In their analysis of the case of Reims, in eastern France, Beckerich et al. (2019) show that HSR has improved the accessibility of both of Reims's stations, but in different ways depending on the type of station. At the peripheral station, access to the HSR network and the cities directly served by this network is better, while access to the capital (Paris) is better from the central station.
- The policies associated with HSR, especially concerning the quality of intermodal management at HSR stations. As Givoni and Banister (2012) point out, the train's journey time is not the only travel time to be taken into account. The amount of time it takes to get to and from stations can reduce the time savings generated by HSR. This is further influenced by supporting transport infrastructures, improving intermodality. Chen (2012) shows how accessibility of HSR stations is unequal among Chinese cities: conditions are much better in the larger cities where HSR stations are also typically intermodal transport hubs.

The Role of HSR with in Attracting Businesses and Tourists

HSR is expected to attract new high-level services in cities where it is implemented. In many instances, it can facilitate the development of business parks through the relocation of some activities (offices) in cities served by HSR, particularly in larger cities (Garmendia et al., 2008). In the case of an international HSR network, Rietveld et al. (2001) highlighted the arrival of international firms as a possible benefit. Concerning the attractiveness of firms around HSR stations, Willigers and Van Wee (2011) consider that HSR plays a role in the attractiveness of cities owing to improved accessibility at the intraregional level for firms already located in the same city or region before the arrival of HSR but not at the interregional level.

Areas around HSR stations also have the potential to attract businesses as a result of increased accessibility. This, however, is not always the case. In France, business parks around peripheral stations do not always attract enough business (Facchinetti-Mannone, 2013). In other cases, central HSR stations provide better intermodality, which allows for a greater concentration of activities in historic core districts. In Reims firms took longer to locate around the city's peripheral station than around its central station, with 70% being local companies (Becherich et al., 2019).

Improved accessibility and connectivity may result in increased productivity and competitiveness for companies located in cities connected to the HSR network. Nevertheless, according to Crozet (2015), the positive impacts of accessibility gains on productivity are conditional.

Improving the accessibility of a destination through HSR can induce the development of meetings, incentives, conferencing, and exhibitions (MICE) tourism, as well as urban tourism. These types of tourism appear to be the main benefactors of HSR, especially if the destination station is located in the heart of the town or city (Delaplace and Bazin-Benoit, 2017). For tourists, HSR replaces the fatigue and inconvenience of driving, congestion, and parking difficulties in city centers, as well as being a cheaper mode of travel. HSR therefore reinforces the touristic attractiveness of a destination and expands its market area. Furthermore, HSR is viewed as a major contributor to climate change efforts, reducing the impact of car and air travel on global emissions.

The results of studies conducted over the last 30 years show unequal benefits from HSR and the reinforcement in competition between tourist destinations (Wang et al., 2012) due to the varying degrees of improvement of their accessibility. An increase in tourist movements is mentioned in big cities in different cities.

Concerning China, a very specific case owing to the extensiveness of its network and the spatial dispersion of its tourist destinations, a certain heterogeneity exists according to location. There is a positive impact on tourism for less-developed western regions, while the impact is moderate for central regions and negligible for the east of the country (Chen and Haynes, 2019).

Another key consideration is the fact that rural tourism does not benefit from HSR, owing to the significant time losses and need for other modes of transport required to reach final destinations. HSR and tourism expansion do not always go hand in hand.

Lastly, a very new area of literature, focusing on the impact of HSR on destination choice, was investigated during the late 2010s (Delaplace et al., 2014). This literature contends that the effects also depend on the destination (the capital or intermediate cities, coastal destinations, theme parks, etc.) and sometimes on the type of tourists (domestic versus international) (Pagliara and Mauriello, 2020).

Furthermore, in many cases, the opening of an HSR service can also induce a decrease in length of stay.

HSR and Urban Projects

HSR can be sometimes described as an incremental innovation (Delaplace, 2017). It adds some new elements to the city. It is used in particular by cities as a tool for urban development and regeneration projects. Two examples include the areas around St Pancras International HSR station in London and Stratford International station, constructed as part of the London's 2012 Olympic Games. In both cases, railway-station districts are at the core of the contemporary urban fabric.

Central stations are renovated and transformed into urban hubs for various flows of transport and shopping activities. HSR generates urban renewal around old stations and urban projects around new stations and this helps to make the station a public space, and not just a rail or intermodal transport hub. By releasing land, HSR services can generate new opportunities in terms of business, residential or commercial real-estate developments (see for example stations in Lille, Le Mans, Reims, and Saint-Étienne in France). Local developers play an important role and their investment is perceived as a signal that leads other (national) developers to invest. These case studies also illustrate the role played by the city and local development agencies to attract developers.

Sometimes, HSR is used to create new centralities around peripheral stations. But these types of projects are not always successful (Beckerich et al., 2019; Facchinetti-Mannone, 2013).

The effects of HSR on urban change are also linked to policies that aim to improve the interconnection between different modes of transport in the city, and also with other cities. The station must be well connected to other transport modes and infrastructures, such as airports, motorways, and interregional rail transport, as well as local public transport (Rietveld et al., 2001), and at different levels (local, national, international, and inter-continental). But this is not always the case. Moreover, well-managed transfers to the city center are also required in the case of peripheral stations. The interconnection of these different networks requires cooperation between different local stakeholders, whether public or private (Delaplace, 2017).

Lastly, HSR can have a positive impact on the image of cities, in terms of modernity and prominence, which is often linked to urban projects around stations and the location of "firms with a status" (Rietveld et al., 2001). More broadly, HSR can raise the status of a whole region but also of the area around stations.

Conclusions

There is no evidence that HSR can always solve transport and regional development problems. One can conclude that the link between HSR and accessibility, economic activities and urban change is place-based: it depends on local considerations and policies. Geography and policies matter in this case!

With this in mind, what will the future hold for HSR? On the one hand, the future seems promising in Europe. The European Commission has expressed a wish for the European HSR network to be completed with interoperability issues resolved by 2050. The length of the HSR network as it stood in 2011 could be tripled by 2030. By this date, it is hoped that rail will be used for the majority of medium-distance passenger transport, as environmental concerns become ever more pressing. A modal shift from air travel to HSR would certainly benefit the environment, however this might be replaced by new induced traffic, contributing to the overall increase in emissions. Moreover, if one considers the total life cycle of an HSR line, the environmental benefits are even lower.

Nevertheless, the future seems to be characterized by HSR projects in numerous countries. In the United States a number of projects are underway, as well as in other parts of the world including Iran, India, Brazil, Malaysia, Egypt, Mexico, and Indonesia.

This paper is dedicated to Moshe Givoni, who passed away in 2019. He was an important researcher in the field of transportation in general and with regard to HSR in particular.

Introduction

Public engagement is an umbrella term referring to the involvement of the public in policy and decision making. The past few decades have witnessed a trend toward increased public involvement in a wide range of national and local government domains, such as science and technology, health, the environment, and transport.

According to the definition offered by the Transport Planning Society (tps.org.uk), transport planning concerns the design, implementation and assessment of policies, plans and projects to improve and manage transport systems at a local, regional, national, and international level. As other key public policy domains, transport planning has wide-ranging implications on people's lives, the economy and the environment. Therefore, public engagement allows those who are affected by, or have a stake in, transport-related decisions to have an input into these decisions.

In order to discuss the topic of "public engagement in transport planning" in a meaningful way it is necessary to critically analyze the terminology used and the underlying concepts, by addressing the following questions in the context of transport policy and planning:

- What does engagement mean? In what forms can the public be engaged?
- Who is/are "the public"?
- What is the rationale for public engagement? What are the advantages of public engagement?
- What aims and objectives does public engagement seek to achieve? How can these objectives be achieved in practice?
- What are the challenges and limitations of public engagement?
- What does successful public engagement look like?
- How has public engagement been used in transport planning to date? What does the evidence say?
- What are the prospects and research agenda for public engagement in transport planning?

The rest of the article addresses each of the questions above.

What Does Engagement Mean? In What Forms can the Public be Engaged?

Other terms are often used as synonyms of public engagement, for example public or citizen participation, civic engagement, stakeholder engagement, collaborative or deliberative governance and so on. Although such varied terminology reflects the different policy and governance domains where public involvement is deployed, the ambivalence in conceptual definition can lead to ineffective application of public engagement.

Public engagement can be differentiated into three main categories according to the flow of information between the sponsors of the engagement (i.e., the decision-making organizations/institutions commissioning public engagement) and those who are being engaged (Rowe and Frewer, 2005). These categories are as follows: public communication, public consultation, and public participation.

Public communication involves the unidirectional flow of information (about a specific policy, plan, program, or project) from the sponsoring organization to the public. The engagement mechanisms (i.e., the activities or tools used to deliver engagement) under this category include communication campaigns using a variety of digital and nondigital media channels, open door events, public hearings or meetings where people can attend in person to view, hear and receive the information being communicated.

Public consultation refers to those public engagement mechanisms whereby the sponsor elicits information from the public, so the information flows unidirectionally from the public to the sponsoring body. This category includes face-to-face consultation and information-elicitation activities such as citizens' panel and focus group meetings, as well as consultation tools that do not require participants' physical presence, such as paper-based consultations, phone and online surveys and opinion polls.

Finally, public participation concerns those engagement initiatives where there is a bidirectional flow of information, or dialogue, between the sponsor and the public. Generally, participatory tools involve some mutual learning between the two parties and produce outputs that reflect (at varying degrees depending on the specific public engagement mechanism used) both parties' values and interests. Participation mechanisms include task forces, advisory boards, action planning workshops, citizens' juries, and consensus conferences.

Who is/are 'the Public'?

The public is also an ambiguous, heterogeneous concept. It normally refers to lay people or ordinary citizens but can also include individuals belonging to professional organizations in the public, private and third sector, as well as partisan or interest groups, who are normally referred to as "stakeholders". It can be argued that even ordinary citizens are stakeholders in that they have a stake in the issue under consideration. For example, in the case of transport policy and planning, citizens interact with the transport system in almost every aspect of their lives, for example as road users, and are affected by the positive and negative impacts of transport, for example the characteristics of the urban environment, traffic congestion, air and noise pollution, and global issues such as climate change.

In transport policy and planning, broad categories of public engagement recipients or participants might include transport service providers (infrastructure and operation); transport users, both individuals such as citizens using a range of passenger transport modes, and organizations such as businesses and retailers that rely on the transport system; transport professionals and consultants; trade unions; local communities; media; and financial institutions (Bickerstaff et al., 2002; Cascetta and Pagliara, 2013). These considerations around the notion of "the public" highlight the fact that there are in fact many publics, with multiple and often contrasting views and interests about a specific transport issue, strategy, policy, or intervention.

What is the Rationale for and Advantages of Public Engagement?

There are several normative and instrumental reasons underpinning the use of public engagement in contemporary democratic societies, which are relevant not just in the transport planning domain but also in other areas of public policy (Bobbio, 2019). From a normative point of view, public engagement can be considered a constitutive element of democratic governance, giving people the opportunity to understand what decisions are being made and for what purposes, so they can have their voices heard and have the possibility to influence such decisions. According to this view, public engagement, especially in its more participatory forms, can be a tool for citizens' empowerment. This can be considered part of a broader shift in governance style, from a conventional top-down, expert-dominated process to a more open, accessible and accountable decision-making process.

Involving the public can also be instrumentally advantageous. On the one hand, decisions made by considering perspectives and knowledge inputs from people bringing different types of expertise and interests can be more robust, lead to better outcomes, create a sense of ownership, increase mutual trust and reduce public opposition. On the other hand, the sole fact of including a diverse range of voices and inputs into decision-making can increase both the actual and perceived legitimacy and procedural fairness of the decision-making process, even when the outcomes may not satisfy the needs of all the involved participants.

What Aims and Objectives Does Public Engagement in Transport Planning Seek to Achieve? How can These Objectives be Achieved in Practice?

The specific objectives of public engagement in transport planning depend on the type and purpose of the decision-making process and the organization responsible for it. Decision making can be about developing transport strategies, local transport plans, and specific transport projects and interventions, ranging from major transport infrastructure projects to smaller local schemes.

A variety of organizations can commission and sponsor public engagement in transport policy and planning. These organizations and institutions are generally those with power over decision-making at local, regional, national, and international level. They may include transport authorities, local and regional authorities, national governments and their departments, agencies and ministries, and supra-national political or policy-setting entities such as the European Commission and other similar institutions.

Public engagement can be undertaken at different stages of the transport planning process, whether this concerns the development of strategies and plans, such as a cycling and walking strategy, or the implementation of an intervention "on the ground", such as a traffic calming scheme or a bus rapid transit line. These different stages are as follows (GUIDEMAPS Consortium, 2004):

1. Problem definition: this stage defines the problem/issue to be solved by the strategy/policy or the transport scheme/intervention. It also identifies who is affected by the problem, those who are responsible to address it and the key performance indicators to be used to monitor how the strategy/policy or schemes/interventions are addressing the problem.

2. Option generation: this stage identifies a set of options for the strategy/policy or features and characteristic of the scheme/intervention.
3. Option assessment: each option is assessed using a variety of techniques to establish its suitability to address the problem.
4. Formal decision-taking: in this phase a formal decision about the strategy/policy or scheme/intervention is taken, with sign off from the relevant responsible authority.
5. Implementation: this stage is about the implementation of the strategy/policy or the transport scheme/intervention, with the development of a management plan, communication and marketing plan, and evaluation plan.
6. Monitoring and evaluation: this stage takes place alongside the implementation phase and assesses the outputs, outcomes and impacts created by the strategy/policy or scheme/intervention.

Decision-making organizations such as municipalities and transport authorities may want to involve the public (i.e., ordinary citizens and stakeholder groups) in one or more of the stages listed above, depending on what their specific objectives are. For example, to develop a cycling and walking strategy, the city council might want to involve interest groups in specific phases of the decision-making process, such as problem definition, option generation and assessment. This in turn informs the various elements and features of the engagement process, which are part of the public engagement strategy.

Key questions for the public engagement strategy are as follows (GUIDEMAPS Consortium, 2004):

- Aims of public engagement: Why is the engagement process being undertaken? Is it appropriate in this context?
- Objectives and scope of public engagement: What elements of the strategy/scheme will be open to input from the public? How will public input be used to influence such elements? How much power will citizens and other stakeholders be given? How will public aspirations be managed?
- Identification of “the public” to be engaged: Who are the people who have a stake in the issue and therefore should be involved in the decision-making process? How can such people be identified? What techniques will be used to access them? Are there any groups who are “hard to reach”? What needs to be done to ensure inclusivity? If a venue is involved, is it suitable and accessible?
- Information and transparency: What information is provided to those people who are being engaged? Is the information adequate to ensure that all those involved can understand it and offer an informed view? How will the involved public be informed about how their input is being used at various stages of the planning process? How will participants be alerted about any unexpected changes in the process? How will feedback be provided to them?
- Engagement mechanisms: How will engagement be undertaken? What tools and techniques should be used? Are the selected engagement techniques best suited to the target groups? What is the required outcome of each engagement activity? What is the public being asked to contribute at each stage of the decision-making process?
- Timeframe: When should different activities take place? Are the start and end points of the engagement process clearly defined and agreed early in the process? Are engagement activities planned early enough for people to understand their added value and be fully engaged?
- Resourcing: Have resources required for the engagement strategy been considered as part of project budgeting? If an independent engagement consultant is employed, has a clear project brief been prepared including budget considerations?
- Evaluation: Is the public engagement process going to be evaluated? How? How will participants contribute to the assessment process? How will the organization use outcomes from the assessment to ensure better engagement practices in the future?

What are the Challenges and Limitations of Public Engagement?

Although public engagement is undeniably a constitutive part of transparent, democratic and inclusive governance styles, and in some cases a mandatory component of specific decision-making processes, it is not a panacea. Public engagement brings a whole host of challenges and limitations, related to the following issues (Flynn et al., 2011).

First, as outlined earlier in this article, the public is not a homogeneous entity which can be easily approached and consulted, but there are in fact many different publics or groups who have distinctive and often contrasting values, views and interests on a given issue. The challenge for the sponsor is about how to arrive at an authoritative decision in the collective interest, in the face of disagreement on what this collective interest might be. Important in this context is to recognize that technical expertise is not always homogenous either, as experts can and do disagree on which facts or evidence can be considered “certain”. Transport presents many “wicked problems” and because, by definition, any planning is about the future, uncertainties abound (Lyons and Davidson, 2016).

Second, different publics possess different kinds and levels of knowledge or expertise on a given issue. For example, transport professionals may bring technical expertise while residents and road users may bring experiential knowledge. However, these different publics may not be able to understand each other’s vocabularies and areas of expertise and may not have the same financial and time resources to be involved. The challenge for meaningful and genuine, as opposed to tokenistic, public engagement (Arnstein, 1969) is therefore about allowing for a truly fair dialogue and mutual learning between publics who may not have the same access to financial, social and cultural capital.

Third, even when public engagement is undertaken with the best intentions and the competent application of carefully selected methods, it may still not produce the outcomes that were originally envisaged. Unexpected events or circumstances might prevent reaching a decision that is accepted, or acceptable, by all the involved publics. Opposition and protest may still occur. Public engagement may not increase mutual trust, and might identify hidden and contested issues which had not, or could not, be

anticipated. Moreover, the bureaucratic and institutional cultures associated with traditional governance styles might be difficult to adapt to more open, participatory types of decision-making, leading to implicit biases in the process that might not be easy to recognize and remove (Irwin, 2007).

What Does Successful Public Engagement Look Like?

The issue of whether and to what extent public engagement is successful brings further questions, for example who defines success, according to what set of criteria? Drawing on an extensive review of the literature (Rowe et al., 2005) offer the following set of criteria as the basis to assess the success of public engagement processes:

- Representativeness: The engaged groups should comprise a broadly representative sample of the population with stakes in the issue under consideration.
- Independence: The participation process should be conducted in an independent, unbiased way.
- Early involvement: The public should be involved as early as possible in the process.
- Influence: The output of the engagement should have a genuine impact on policy/decision-making.
- Transparency: The process should be transparent so that the public can see what is going on and how decisions are being made.
- Resource accessibility: Public participants should have access to the appropriate resources to enable them to successfully fulfil their brief.
- Task definition: The nature and scope of the participation task should be clearly defined.
- Structured decision making: The participation exercise should use/provide appropriate mechanisms for structuring and displaying the decision-making process.
- Cost effectiveness: The engagement process should be cost effective and proportionate to the issue under consideration.

How has Public Engagement been used in Transport Planning to Date? What Does the Evidence Say?

Despite its growing importance and diffusion, the practice of public engagement is less developed in the transport planning domain compared to other areas of public policy, such as science and technology policy and health care (Nared, 2020). Nevertheless, some form of public engagement in transport decision making is generally required by law in most democracies across the globe.

It is perhaps not surprising that public engagement in transport planning appears to have received comparably less attention from the academic community than engagement in other policy and planning sectors. A review for the EU-funded project Challenge (Lindenau and Böhler-Baedeker, 2014) reveals that public engagement in transport planning varies widely across Europe, with several countries such as Germany, France, the UK, and Belgium having formal, mandatory consultation procedures for mid- and large-scale transport projects as well as for the development of transport strategies and Sustainable Urban Mobility Plans (SUMPs). A few countries deploy innovative engagement mechanisms such as participatory citizens' workshops and participatory transition management initiatives (e.g., in the Belgian city of Ghent).

A survey of 34 cities from across Europe and beyond, exploring their transport planning practices including the use of engagement mechanisms, found that most cities involved both stakeholders and citizens, but with varying degrees of engagement (Lindenau and Böhler-Baedeker, 2014). Stakeholders, such as public transport providers and sustainable transport organizations, were predominantly involved in the identification of transport and mobility problems, but only in few cases in other planning stages (e.g., specifying the vision and objectives, identifying possible solutions). Retailers and customers were seldom invited to participate. According to the survey's results, key barriers to successful public engagement include the lack of political will, limited financial and staff resources, lack of skills to undertake engagement, failure to establish a plan or strategy for participation, lack of interest from the public, an imbalance between different stakeholders' effective ability to provide input, lack of engagement culture especially in Eastern European post-communist countries.

Similar results emerged from a very recent survey-based study of the experience with participatory transport planning in the eight European metropolitan regions of Ljubljana, Oslo, Gothenburg, Helsinki, Budapest, Rome, Porto, and Barcelona (Nared, 2020). The findings show that public and stakeholder engagement varies according to the geographical scale involved. Participants' engagement is greater at the local level, where transport plans and interventions are perceived as more relevant to those involved. The participatory planning process takes longer than traditional top-down processes, but it can facilitate the implementation of the project/measure when the additional resources and time are justified. The survey found that the engagement process benefited from an inclusive selection of all the involved interest groups, the provision of an experienced engagement facilitator and, above all, transparency in demonstrating how the engagement process and its outcomes influenced the final plans, policies or interventions. Although significant differences in engagement practices and outcomes were found between the countries and regions involved, with Scandinavian countries displaying a more participatory planning culture, the use of participatory methods in transport planning is becoming increasingly important across Europe.

Most of the academic literature on the practice of public engagement in transport planning focuses on case studies from the UK. The emergence of public engagement in transport planning in the UK can be dated back to the late 90s, when a series of key policy documents issued by the Labour Government introduced the concept of engagement to put power closer to people, strengthen citizens' rights, make national and local government more open and accountable, and to ensure that public institutions were more

representative (Bickerstaff et al., 2002). Until then, transport had been a sector with very limited historical experience of public participation in the decision-making and policy process, which traditionally had been dominated by technical experts and politicians.

The 1998 White Paper on an integrated transport strategy announced the introduction of 5-year Local Transport Plans (LTPs), to be developed by highway authorities in England to set out investment proposals and targets in local transport matters such as traffic reduction, air pollution, public transport and active travel. Although the White Paper and subsequent official guidance documents required local authorities to undertake “extensive consultation” with the public and other stakeholders and that their opinions should “make a difference”, details of how this was to be achieved in practice were missing, as well as specific guidelines on who to involve and in what stages of the decision-making process. An evaluation of the early experience with public engagement in transport planning (Bickerstaff et al., 2002), based on a review of 58 LTP documents and a survey of the English local authorities responsible for their production, found that public engagement had been taken up almost universally across the sample, but with considerable variation in terms of the type and level of engagement. Information provision and consultation seemed to be the norm, but the study also found evidence of efforts to deploy more innovative forms of participatory engagement. The study concluded that, for most of the surveyed local authorities, the engagement process resembled the realms of tokenism on Arnstein’s ladder of citizen participation, due to such weaknesses as little engagement with different sectors of the public, few opportunities for effective deliberative interaction and mutual learning, and low policy transparency.

The Local Transport Act 2008 gave local authorities in England more autonomy and flexibility to produce LTPs in terms of their objectives, indicators, timescales and policy instruments. A content analysis of LTPs produced after 2008 revealed that some of the weaknesses identified above were still present and had a considerable impact on the inclusivity of these decision-making processes, especially for social groups more at risk of transport-related social exclusion, such as lone parents and ethnic minorities (Elvy, 2014).

Further insights on the practice of public participation in transport planning are provided by High Speed 2 (HS2), a major (and controversial) transport infrastructure project creating a high-speed rail link between London and the north of England (Cohen and Durant, 2019). Their critical analysis of the engagement process deployed in HS2 Phase I found that the approach was a classic example of “decide, announce, defend” (DAD), suggesting that such traditional and much criticized top-down approaches to decision making are still considered the default option.

Recent experiences in South American countries such as Brazil and Chile suggest that improvements in the practice of public participation are indeed taking place, with examples of local authorities deploying innovative digital technologies alongside more traditional face-to-face engagement techniques to encourage participation from a wider range of publics in the production of urban mobility plans or major transport infrastructure (Sagaris, 2018; Worker, 2014). However key challenges still persist, similarly to what has been found in other countries, notably the lack of institutional culture and practical arrangements that could facilitate more deliberative, collaborative participatory processes, and make them an established component of everyday transport planning.

Public engagement is an increasingly important and institutionalized component of transport decision-making also in North America and Australia. Studies looking at examples from these areas note that, whilst citizens’ participation is certainly a step forward towards more democratic decision-making processes, public engagement can add complexity rather than solve it.

A comparative analysis of citizen participatory mechanisms in Detroit, Michigan (a Citizens Advisory Committee involved in the development of a regional transit master plan) and Hamilton, Ontario (a Citizens’ Jury involved in the establishment of light rail transit) found that both these participatory mechanisms were considered important and useful by both the participants and the politicians who had established them. However, the conclusion was that neither mechanism had a significant impact on transit policies and outcomes, which were instead shaped by a range of political divisions at the local and regional level that no amount of public engagement could address (Sutcliffe and Cipkar, 2017).

Over the past few decades, transport policy in Australian cities has been embedded within metropolitan-wide strategic plans together with land use planning. The development of such plans has become an increasingly participatory and consensus-based process, designed around deliberation and inclusive public dialogue in the form of citizen juries, citizen panels and large-scale town hall meetings (Legacy et al., 2017). However, a critical analysis of three major inner-city road projects in Melbourne, Sydney and Perth revealed that the engagement process did not adequately and openly discuss the harder questions about infrastructure project priorities. Namely, how these projects should be financed and who will be served through the enhanced accessibility they are said to provide.

Conclusions: What are the Prospects and Research Agenda for Public Engagement in Transport Planning?

Public involvement in some form or another has become a feature of democratic governance, and transport policy and planning are no exception. However, despite the growth in engagement exercises within transport decision-making, in-depth evaluations of the extent to which these initiatives are successful, as well as of the underlying barriers and enabling factors, are very few. It seems that the research agenda proposed in 2002 by Bickerstaff and colleagues (Bickerstaff et al., 2002) is still very relevant today: what can public involvement methods achieve in transport-related decision-making processes? How far can public engagement deliver substantive outcomes in terms of policy, mutual learning and broader democratic benefits? What effects should public engagement have on transport policy and decisions? What can public engagement not achieve? How can public engagement mechanisms best be used to enhance transport planning? How can or should we evaluate and learn from the experience gained so far?

Regions and cities are currently faced with significant challenges such as climate change, air pollution, population growth and other key socio-economic trends. Transport represents both a cause and a solution to these issues, therefore more effective public engagement may be a way to ensure that policy decisions reflect shared visions of what the future should look like.

Scope

This article focuses on long-distance passenger travel demand – the reader is referred to other articles in this Encyclopedia for a discussion of freight transportation and of infrastructure aspects in the long-distance segment. The focus of the discussion is mainly on private travel, given its prevalence in the long-distance travel segment, although we refer to business travel throughout.

Definition

While the concept of “long distance travel” (LDT) is commonplace in transportation research, a precise definition has remained elusive. Broadly speaking, LDT is defined based on one or more of the following criteria:

- spatial distance
- travel time
- frequency and regularity
- overnighing

Within transportation research, LDT is mostly defined based on spatial distance thresholds, although a range of values are used in the literature, with considerable variation across countries and between studies. The focus on spatial distance generally reflects an interest for transportation volumes and their negative consequences, which tend to be proportional to mileage. In countries in the Global North LDT accounts for a small share of trips, but for a significant share of total mileage (roughly between 30% and 50% depending on the country and method), and for an even higher share of emissions.

There is a parallel tradition of research, which defines LDT in terms of temporal duration. This reflects an interest for the (negative) consequences on individual well-being (e.g. health, social relationships) of spending an excessive amount of time traveling. Notably, the determinants and implications of “long-distance commuting” (whether on daily or weekly basis) have drawn much attention. Studies on “transport poverty” also highlight how excessive travel time can result in problems of time poverty—that is, reduced participation in activities that are essential for social inclusion—particularly in the Global South.

LDT is also often defined in terms of (low) frequency and (lack of) regularity, as when it is contrasted to “daily mobility” or “everyday travel”. Some definitions see LDT (or segments of it) as taking place outside a person’s “usual environment,” although this can be challenging to define precisely. The question of whether LDT is infrequent and irregular is a complex one. LDT is a ‘rare event’ among the population, as well as for most individuals, but at the same time there is a minority of frequent long-distance travelers for whom this is a regular occurrence (e.g., daily long-distance commuters, frequent flyers). These are responsible for disproportionately high shares of LDT mileage, which makes them worthy of investigation.

Finally, LDT is sometimes defined based on overnight stay in a non-home location, for two main reasons. First, overnighing-based definitions of LDT help reduce recall error in household travel surveys, as it is a memorable event for respondents. Second, overnight stays potentially generate tourism revenue, which explains why the official definition of tourists is “persons traveling outside their usual environment for all purposes of visit, and staying overnight but for not more than one consecutive year” (UNWTO–UNEP–WMO, 2008, p.121). Tourism is responsible for an important share of LDT, and this is drawing increasing attention from both transportation and tourism researchers.

There are thus multiple criteria to define LDT, and these are not always aligned. For some forms of LDT (e.g., occasional flight holiday to distant destination), all of the above criteria apply, while for others (e.g., daily long-distance commuting by car), only some of them do. This diversity of perspectives is not a limitation, as it reflects the multiplicity of practical interests that underlie research on LDT. Different definitions of LDT are appropriate, depending on whether the focus is on climate, quality of life or tourism. This does however require researchers to be explicit about the definitions they adopt, about the rationale for them, and to position themselves with respect to alternatives. It also raises issues for data collection, as discussed below.

Another way to deal with the definitional complexity of LDT is to see it as an umbrella concept covering multiple travel segments. [Frick and Grimm \(2014\)](#), for example, suggest a classification based on three criteria (trip purpose; overnighting; whether the trip is outside of one's usual environment), and consisting of eight segments:

- personal day trips
- long-distance everyday personal trips
- long-distance commuting
- long-distance everyday business trips
- business day trips
- holiday trips (5+ days)
- short holiday trips (2–4 days) and other personal overnight trips
- overnight business trips

Alternative segmentations have been proposed, some of which are based on distance. Empirical studies show that mode choice for long-distance journeys is sensitive to trip length, with cars dominating for “shorter” long-distance trips, and a greater share of rail and air travel for journeys over medium and very long distances.

Measurement and Methods

Even when LDT is defined in terms of spatial distance, its empirical assessment remains challenging. Accurate measurement of this travel segment is beset by methodological problems, some of which are inherently difficult to solve. Data collection on LDT tends to be fragmented across countries, disciplines, and surveys, which creates further challenges. The result is that our understanding of LDT lags behind that of everyday urban travel, a situation which contributes to its low salience on the research and policy agenda.

LDT is captured to some extent in conventional household travel surveys but, being a “rare event” for most individuals, it does not fit with the short-reporting period of most travel diaries. Hence a dedicated module on LDT is often included, with a longer reporting period (although this varies widely – from one week to 12 months). This, however, raises other methodological issues, mainly related to high response burden. In retrospective survey instruments, this tends to result in selective recall, soft refusal, and ultimately underreporting of long-distance trips ([Janzen et al., 2018](#)). Prospective instruments have their own issues in terms of respondent drop out. These risks must be traded-off against each other, as they all have implications for the accuracy of LDT estimates.

Other reasons for the underestimation of LDT are the undersampling of (inherently hard-to-reach) frequent long-distance travelers, and the multimodal nature of much LDT, as access and egress modes to transportation nodes like airports are not well-captured in travel surveys. Also, travel at the destination as part of overnight tours tends to be underestimated (or even not captured at all).

The difficulty of capturing LDT with conventional travel surveys has led some countries to develop dedicated LDT surveys. To these must be added national tourism demand surveys, and a range of tourism-related surveys conducted by public and private organizations. As these surveys differ in key methodological aspects such as operational definition of LDT, reporting period, inclusion of international travel, etc., the result is a fragmentation of the data landscape, which works against a comprehensive assessment of LDT levels and trends.

Methodological differences across countries add another layer of complexity. A significant share of LDT is across borders, particularly in world regions like Europe. Yet national surveys differ in key methodological details such as whether LDT is defined in terms of distance or overnighting, distance thresholds (ranging from 40 km to 100 miles), reporting period, and whether international travel is included. While there have been attempts to internationally harmonize LDT survey methods, to date they have had limited success. Internationally comparative studies of LDT are thus rare and beset by high levels of uncertainty.

Overall, data fragmentation and lack of harmonization make it necessary to integrate data from diverse sources in order to obtain overall estimates of LDT at a country (e.g., [Frick and Grimm, 2014](#)) or world region level ([van Goeurden et al., 2016](#)). This is suboptimal and can result in inconsistent measurement.

More broadly, the shortcomings of conventional household survey instruments in capturing LDT have led researchers to experiment with “passive data collection methods” based on mobile devices, although these have their own methodological shortcomings in terms of technical accuracy, data cleaning requirements, and sampling representativeness. The limited information available on individual attributes also constrains the opportunities for data analysis. Nonetheless, the results of studies based on mobile device data suggest that LDT demand is vastly underestimated by household surveys. [Janzen et al. \(2018\)](#) for instance analyzed mobile phone billing data of millions of French users, finding long-distance trip rates twice as high as those reported in the national travel survey.

Trends

While reliable figures on long-term trends in LDT are scarce, existing evidence points to a rapid growth since the mid-twentieth century. Schäfer et al. (2009) show how the large increase in global passenger travel distances between 1950 and 2005 was driven by a shift from low- to high-speed transportation. Their analysis shows that when a country reaches average mobility levels of circa 30 km per person per day, the modal share of the automobile starts to decline (on a pkm basis) in favor of “high-speed transportation modes” such as air travel and high-speed rail. This is associated with a shift from short- to long-distance travel, and a growing share of leisure trips. In high-mobility countries, there is also a shift from domestic to international LDT, as observed, for example, for Sweden (Frändberg and Vilhelmson, 2011). Globally, international tourist arrivals increased by more than 20 times between 1950 and 1995, far outstripping population growth (Gössling and Peeters, 2015).

Trends in the last three decades are better documented, and show the continuation, and possibly acceleration, of the trends just described. Global estimates (UNWTO and ITF, 2019) show that between 2005 and 2016 there has been a rapid increase in overnight tourism travel both domestically (+119%) and internationally (+65%), while same-day trips have doubled. van Goeuverden et al. (2016) find an increase in LDT trips (+8%) and volume (+27%) in Western Europe between 2001 and 2013. Since short-distance travel has stagnated over the same period, this results in an increase in LDT’s share of total pkm. Similar trends have been observed in several Global North countries, with faster growth in the private and leisure travel segments than in business travel. In countries like Sweden, growth has been particularly rapid for international travel with, for example, Larsson et al. (2018) finding a doubling of international flights between 1990 and 2014.

Overall, these historical trends suggest a continuous spatial extension of overall mobility (Frändberg and Vilhelmson, 2011). The “peak car” or “peak travel” phenomenon observed in some countries in the Global North could thus reflect a shift towards faster, long-distance travel modes (notably aviation) and international mobility (which is poorly captured in national travel surveys), rather than a turning point. Notably, there is suggestive evidence that peak car among young adults may be offset by increasing levels of long-distance, international, and air travel.

While it is often assumed that this rapid growth has gone along with a reduction of inequalities in participation to LDT, the empirical evidence is contrasted. Demoli and Subtil (2019) for example, show that the distribution of LDT among French residents has become more unequal between 1974 (when 10% of the population was responsible for 30% of LDT mileage) and 2008 (when this figure reached 60%).

Forecasts of future travel demand (Schäfer et al., 2009) show a continued increase, driven by the continuing shift towards high-speed transportation modes, whose share of total pkm is predicted to reach 45%–70% in “industrialized regions” and 15%–30% in “developing economies” by 2050 (assuming unconstrained infrastructure expansion and no travel demand management). Schäfer et al. (2009, p.51) argue that in such a scenario, “long-distance trips with a short stay at destination may become more normal,” as would associated “multilocal” and global lifestyles. Tourism forecasts (UNWTO and ITF, 2019) predict a 74% increase in overnight trips between 2016 and 2030, and a doubling of same-day visitors, with faster growth in the Asia and Pacific region, and an associated increase in air travel. At the time writing, it is not clear to what extent the COVID19 crisis of 2020 will change these forecasts.

Evidence on trends in work-related LDT is sparser and more ambiguous. Studies from the Global North generally show an increasing trend in long-distance commuting (e.g., Frändberg and Vilhelmson, 2011; Frick and Grimm, 2014), although this varies considerably between countries, over time, as well as depending on the (time- or space-based) definition. Viry et al. (2015) compare retrospective life-course data for three cohorts (born between the 1952 and 1981) in four EU countries and find no evidence of an increase in long-distance commuting and work-related “overnighting” over time.

Macro Drivers of Growth

The structural drivers of LDT growth are manifold and are investigated in various disciplines and strands of research. Schäfer et al. (2009) explain increasing travel demand since the 1950s simply as a result of economic growth, technological progress, and increasing affordability of faster, motorized travel modes. Yet the decreasing cost of travel, improvements in transportation and telecommunication technologies, and the expansion of related infrastructure tend to result in an expansion of activity spaces and social networks, which in turn encourage more LDT. This can be defined as the “institutionalisation” of LDT, that is, the self-reinforcing process whereby increasing levels of LDT become locked-in (Frändberg and Vilhelmson, 2010). With regard to tourism, further drivers of growth include increases in paid holiday time, the softening of border travel restrictions, the diffusion of information and communication technologies, as well as the globalization of technology, trade, and production (Scott and Gössling, 2015), which has direct implications for business travel. With regard to air travel, the rise of new business models such as low-cost carriers has played an important role.

Overall, greater ease of LDT has encouraged new lifestyles and practices, variously referred to as “transnationalism,” “transmigration,” and “residential multilocality,” which blur the distinction between migration, residential relocation and circular mobility. These may be more common among well-educated younger generations, and the youth travel segment is a key area of growth for the tourism industry. Transnational and multilocal practices are predicated on high levels of LDT, although their impacts on transportation have not received the attention that they deserve to date.

Looking forward, [Frick and Grimm \(2014\)](#) list a number of drivers that might contribute to future LDT growth including demographic trends (ageing, migration), as well as spatial (urbanization), economic (expansion of the service sector), and cultural (individualization) developments.

Determinants of Long-Distance Travel Behavior

Transportation research shows that multiple factors explain differences in short-distance travel behavior between individuals, including sociodemographic, economic, sociopsychological, and spatial attributes. The role of these factors in explaining LDT is comparatively less well understood, although existing evidence highlights both similarities and differences.

With regard to income, previous research has shown that LDT is more strongly associated with income than daily travel, and air travel is more strongly associated with income than car travel, even after controlling for intervening factors. Other socioeconomic characteristics consistently associated with higher levels of LDT in multivariate regression studies include (full-time) employment, being in education, higher levels of education, and male gender, while old age and living in households with children tend to reduce LDT.

Most studies on environmental attitudes and daily travel behavior find only a weak association between the two, and substantial evidence suggests that this “attitude-behavior gap” is even more pronounced for long-distance, holiday, and air travel. [Czepkiewicz et al. \(2019\)](#), on the other hand, find a strong association between cosmopolitanism and emissions from international travel, suggesting that LDT might well be influenced by other attitudinal dimensions.

While much research shows that in compact, inner city areas with mixed land use daily travel distances, (particularly by car) are lower, the relationship between urban form and LDT is in the opposite direction. [Czepkiewicz et al. \(2018\)](#) review the empirical literature on this point (mostly from Europe), concluding that levels of (non-business) LDT are higher in dense urban areas, even after controlling for common socio-economic predictors. This finding is mostly driven by international and air travel – when these are excluded, LDT levels are higher in low-density and peripheral areas. Five theoretical explanations for this relationship have been put forward ([Czepkiewicz et al., 2018](#)):

- a rebound effect, whereby the time and money saved on car use in everyday life are spent on LDT
- the “compensation hypothesis,” whereby for example, urban residents make up for lack of private green space with LDT to natural areas
- better access to LDT infrastructure
- lifestyles and sociopsychological characteristics conducive to more long distance travel
- greater dispersion of social networks

Overall, [Reichert et al. \(2016\)](#) argue that socioeconomic attributes affect emissions in daily travel and LDT in the same direction, while spatial attributes have opposite impacts on the two segments. A possible exception here is migration background, with some research showing that migrants have lower levels of car use, but higher levels of air travel and related emissions, partly because of more geographically dispersed social networks (see e.g., [Mattioli and Scheiner, 2019](#)). Yet to date most quantitative studies of LDT determinants do not consider migration background or social network dispersion.

The socioeconomic determinants of business LDT are broadly consistent with those of LDT as a whole, although further work- and workplace-related factors need to be considered such as sector of employment, business sector, position within organization, and the company’s locational and organizational strategies ([Aguilera and Proulhac, 2015](#)).

Multivariate studies on the determinants of long-distance commuting show similar results, with male gender, higher income, and higher education levels having a positive effect. Living in dense urban areas, and length of residence in the local area tend to reduce the chances of commuting over long distances, as does living in households with children (although this applies mostly to women).

Policy Issues

Historically, LDT has been a relatively overlooked topic in transportation studies and policymaking despite its disproportionate importance in terms of mileage, infrastructure use and associated impacts. It deserves greater consideration, not least due to its rapid growth and significant policy implications. We discuss two of them here: the contribution of LDT to climate change, and social inequalities in LDT demand.

The contribution of LDT to climate change is a topic that falls through the cracks between different sectors, disciplines and data sources. Accounts of sustainable transportation tend to have an urban bias, overlooking non-urban travel even though it accounts for 60% of global passenger transportation volume, and for two-thirds of projected growth to 2030 ([UNWTO and ITF, 2019](#)). Similarly, climate change has only recently gained prominence as a topic in tourism research, although estimates suggest that tourism travel-related emissions (of which half due to air travel) represent 22% of total (both passenger and freight) transportation emissions and 5% of overall man-made CO₂ emissions ([UNWTO and ITF, 2019](#)). These figures are lower-bound estimates, as 50% of travel-related tourism emissions are for aviation, where non-CO₂ climate-forcing impacts significantly magnify the global warming effect (see for example [Reichert et al., 2016](#)).

Historically, efficiency improvements in per passenger emissions have been more than offset by rapid growth in tourist numbers, a trend that is likely to continue. Since there is no easy “technological fix” to aviation emissions, some form of demand management policy will be necessary. This enhances the importance of understanding the dynamics and determinants of LDT demand. Emissions from personal travel could be reduced more effectively if the longest distance trips in relevant activity domains and geographies were the target of decarbonization or demand management. Conversely, reducing passenger transportation emissions will be extremely challenging unless LDT is addressed.

A second, less discussed policy issue is that participation in long-distance travel is very skewed toward privileged social groups. There are several good reasons to question inequalities in LDT, including: questions around the fairness of allocating public resources to the expansion of LDT infrastructure; the disproportionate contribution of frequent long-distance travelers to environmental externalities; the possibility that some forms of LDT may be instrumental to social inclusion, particularly as activity spaces and social networks have expanded.

Yet given the environmental impacts of LDT, the solution can hardly be a generalized increase in levels of travel activity – which points to trade-offs between the two policy issues discussed here. This is manifested for example, in the case of public investment in high-speed rail, which is sometimes aimed at encouraging a modal shift from air to rail, but can also be seen as inequitable, as it disproportionately benefits the high-income users of long-distance rail. As the importance of LDT becomes apparent, issues such as this will become more present in the transportation debate.

Introduction

Urban freight policy is the set of policies, mostly at local levels, that target the urban movement of goods in order to reduce its negative impacts (pollution, energy consumption, congestion, accidents) and increase its benefits (provision of urban jobs, promotion of the economic vitality of cities, city logistics innovation). With the development of e-commerce and fast deliveries, urban freight challenges have increased in cities worldwide and have become a topic for policy. The recent covid pandemic has raised awareness of urban freight from policy-makers. This is true for local governments but also at State and higher (European Union, US Federal level, etc.) levels of government. Guidelines are available for cities today, providing data and examples of best policy practices, but several areas of policy intervention are still missing, such as drastic reduction in CO₂ emissions from urban freight, or training and career development in distribution and warehousing. After an initial section on urban freight impacts, the main policy initiatives in urban freight are discussed: access rules and low emission zones; urban freight consultation initiatives; promotion of innovations; urban freight planning; curbside management; promotion of clean delivery vehicles; and data and modelling.

Urban Freight Impacts Require New Policies

Urban freight issues meet societal demands and therefore policies. One pollution peak after another in New Delhi (but also Paris or Milan) bring to the forefront the health risks posed by diesel, used by almost all delivery vehicles. Urban freight emits 52% of transportation-related NO_x in Paris (Coulombel et al., 2018). The stakes are also economic, since air pollution damages the image of major cities. Urban freight is also responsible for 20%–30% of transportation-related urban CO₂ emissions and contributes to climate change. This share is currently growing, and the OECD predicts that it may reach 50% by 2050. Protection against risks, from extreme weather events to terrorism, to pandemics, is a priority for local action, and among the targets that need protection are warehouses close to cities, especially those storing hazardous materials. The organization of the distribution of goods is at the forefront of the plans to prepare cities for exceptional events, such as recently demonstrated by the covid pandemic. On a more common occurrence, technological developments and new forms of consumption have made freight issues very visible for residents and policy-makers. When Amazon set up an urban warehouse in the center of Paris in the summer of 2016, the discussion began at the highest level: “This kind of facility is for retail, even if {Amazon} claim{s} to do logistics. What I am defending is not that they should be banned, but that they should fit into this retail qualification that corresponds to what they do and that they should be subject to the same rules” (Anne Hidalgo, Mayor of Paris). Self-employed couriers on bicycles or motorbikes on the streets of large cities worldwide pose new road safety problems and their situation challenges labor law (Dablanç et al., 2017). These on-demand “instant” delivery platforms also bring thousands of job opportunities to young people and migrants, re-introducing low-skilled jobs into urban centers.

Faced with these new challenges, urban freight transportation policies are taking shape. According to a recent count (Letnik et al., 2019), out of 129 medium and large European cities, 15 have adopted a “freight plan” and 84 include logistics measures in their urban mobility plans. Involvement in urban freight for the public sector can be manifold and at various levels. Municipalities are in charge of the urban road network, which is heavily impacted by commercial vehicle traffic. Cities are also interested in local economic development, and therefore have to make sure that the provision of goods and logistics services is adequate. They control land uses, including the land necessary for logistics activities (warehouses and terminals), and are in charge of local traffic and

parking regulations, including all regulations that relate to delivery vehicles. Finally, cities are concerned with environmental and social issues, which are strongly associated with urban freight activities. Metropolitan-wide agencies in charge of transportation infrastructure and metropolitan master plans are also involved in urban freight issues. Higher levels such as regional, national or federal, look at urban areas and promote policies related to air quality, climate change, job creation, and economic development. They set legislation such as air quality standards, organize data collection framework, and research programs that have a direct impact on urban freight local policies. This is also true at an international level, with an increasing number of organizations publishing reports and guidelines on urban freight (CAF, 2019). Major events such as the organization of the Olympic games provide opportunities to organize a change in urban freight operations citywide. After the 2012 Olympics for example, London developed a clear city logistics strategy (Browne et al., 2014). In many other cities, major infrastructure projects such as the implementation of a tramway or a subway system can also play that role.

Despite these many drivers, mandates and potential objectives, actual strategies of local public policies regarding freight and logistics are quite modest. Many cities still organize their urban freight policy around truck traffic and parking management. They view commercial traffic as something that should be banned or at least strictly regulated, and not as a service they should help organize. Local policies are often very parochial and can be conflicting. In the following sections, we address the main areas of policy intervention, mostly at the local level, and we identify achievements and remaining challenges.

Access Rules, Low-Emission Zones, Tolls to Organize Urban Logistics

The tool that local governments dealing with freight activities use primarily is truck access restriction. These restrictions are based on various criteria such as time windows, or the weight and size (length, surface) of the vehicles. The most famous truck ban is the London Lorry Ban, in place since 1975. Heavy goods vehicles over 18 tons of gross weight cannot circulate at night and weekends. All trucks in Seoul, Korea have been banned since 1979 from the central areas during working hours. Truck access rules based on weight or size policies have several drawbacks. They tend to promote small capacity vehicles (vans, light trucks), which increases total congestion and reduces the efficiency of urban freight. Regulating truck access requires enforcement and control, meaning a sufficient and well-trained staff. Truck access rules are also very local and can contradict each other from one municipality to another. In metropolitan Lyon, in France, there are more than 50 different regulations on truck weights, dimensions and delivery schedules (Heitz and Dablanc, 2019), forcing delivery drivers to choose which of the rules they will follow.

The most recent trends in access restrictions are environmental standards and road pricing. Both can be combined, as is the case for the London congestion charge. Urban tolls are not specific to commercial vehicles, while many environmental zones or “low emission zones” and “clean air zones” are. In cities worldwide, more and more rules target the age of vehicles or their level of atmospheric emissions. More than 200 major European cities have established low emission zones (<http://urbanaccessregulations.eu>). London is the largest (1500 km²) and most restrictive. It is well monitored, with hundreds of cameras recording vehicle plate registration numbers. It concerns heavy goods vehicles and large vans. An “ultra low emission zone” (ULEZ) applies to the city center, allowing only Euro 6 vehicles (built after 2014). By March 2021, only Euro 6 commercial vehicles will be allowed in all Greater London. Greater Manchester has also brought itself into line with London standards. In Madrid, Spain, the rule is based on a national vehicle classification. All Spanish cities should have a plan similar to Madrid’s from 2023, at the request of the central government. Several European cities—Amsterdam, Oslo—now plan for “zero-emission zones” (ZEZ).

New enforcement technologies have increased the efficiency of truck access policies. Automatic control systems such as automatic number plate recognition cameras, mobile enforcement, vehicle positioning and on-board equipment have been introduced in many cities in Asia and Europe. This technology comes at a cost and generates controversy mainly over privacy issues. Urban tolls for goods transport vehicles are, for their part, rare in cities. Singapore Electronic Road Pricing has operated since 1998, with specific fees for commercial vehicles. Oslo, Norway and Stockholm, Sweden, have tolls. Road pricing raises the question of price sensitivity, as operators only gradually change their transport methods when faced with a congestion charge. Since the introduction of the congestion charge in the inner city of London in 2003, the number of lorries in the area has remained almost stable, while at the same time the number of private cars has fallen by more than a third. Milan, which differentiates tariffs according to the age (and therefore pollution) of the vehicles, has a different experience. The average number of daily delivery vehicles in the restricted zone was 13,174 before the introduction of the system and 10,500 afterwards, with no apparent impact on the freight supply of the center of Milan (Rotaris et al., 2009). An interesting effect of pricing or access regulations based on the age of trucks is that they force small urban freight operators, often contractors to large companies, to change their operating practices and modernize.

The promotion of night deliveries (or rather early morning/late evening), and in parallel the reduction of noise caused by deliveries, are new targets of municipal policies. New York City provides subsidies to encourage businesses to deliver at off-hours. According to a survey made in New York City, businesses most likely to change to off peak deliveries are shippers doing their own deliveries (own account transportation), and receivers open during extended hours such as restaurants (Holguin-Veras, 2008). The PIEK program in the Netherlands covers all aspects of research and regulation to reduce noise from night deliveries: rolling stock, handling equipment and driving practices. The national government provides financial help for operators investing in silent delivery equipments, which are vehicles and handling equipment generating noise emissions below 65dB, for night deliveries. Tests have shown that companies delivering at night save 30% in delivery cost and 25% in diesel consumption (Fig. 1).

Figure 1 Encouraging silent delivery vehicles in Paris, France.

Negotiating With Freight Stakeholders

Cities are setting up consultation processes with delivery companies and their organizations. These groups provide collaborative opportunities between private companies and local administrations that otherwise are not willing to work together. “Freight Forums” or “urban logistics charters” have become part of local communities’ vocabulary. Examples are the Charter for Sustainable Urban Logistics in Paris signed by 80 carriers’ and shippers’ associations in 2013, and the Freight Quality Partnerships of the various boroughs of London, for which Transport for London, the Greater London transport agency, is responsible for overall coordination. The process of Living Labs, bodies for consultation, design and implementation that accompany an urban project, often has a variation for urban logistics (CITYLAB, 2019). The Multiactor multicriteria analysis (MAMCA) is proposed by Macharis et al. (2019) as a tool to better involve urban logistics stakeholders. It uses stakeholder objectives as evaluation criteria of the different solutions that are considered. More focused on research and experiments, the “Urban Freight Lab” of Seattle in the United States brings together the municipality, the University of Washington (which runs the laboratory) and the logistics, transportation and real estate industries. When these bodies have reached a certain longevity, they act as a forum for negotiating measures such as setting an urban pricing scheme or setting up a labelling system for carriers, like the Fleet Operator Recognition Scheme (FORS) in London, UK, which awards medals (bronze, silver, gold) to delivery companies on the basis of their environmental and social performance. Certification provides operators with a competitive advantage when bidding for contracts. It gives companies access to data, benchmark information, and training programs for their drivers.

Discussion forums between cities exist at a trans-national level, such as within POLIS, a network of European cities and regions dedicated to transport policies which leads numerous actions on freight transportation, or the Alliance for Logistics Innovation through Collaboration in Europe (ALICE), one of whose committees is dedicated to urban freight. ALICE’s roadmap for 2019 included “the search for new, optimized and sustainable urban logistics business models”. While such business models may not emerge from a European think tank, however well-intentioned it may be, but from the market’s response to actual regulatory or financial access conditions put in place in cities, platforms such as ALICE provide networks promoting the exchange of best practices.

In Search of the Latest Innovations

Many local governments are promoting innovation in urban logistics with efficiency and/or environmental mitigation as objectives. Electrically assisted cargo bikes are increasingly popular with cities. A world cargobike festival took place in Groningen in the Netherlands in June 2019 and another was held in Dublin, Ireland, a few days later, supported by the municipalities. Local administrations open bus and bike lanes to cargobikes, providing these new urban delivery vehicles with a considerable competitive advantage over vans and delivery trucks. In 2019, New York City authorized pedal assist cargo bikes from Amazon, DHL and UPS to operate in the city, using some of the municipal on-street unloading/loading zones at no fee. The rapid development of bike lanes following the covid pandemic further increases cargo-bikes’ advantage. On a more futuristic level, the city of Reykjavik in Iceland authorized Flytrex, a designer of unmanned automated vehicles (UAVs), and retail distributor Aha to organize a regular drone delivery line over one of the city’s bays. Swiss Post operates the drone delivery of pharmaceutical products in partnership with the municipalities of Zurich and Lugano. At the State and Federal levels in the US, authorizations are provided to delivery companies to test and operate drone delivery lines, such as UPS on campuses, and FedEx and Walgreens in association with Wing. Street robots such as Nuro, sidewalk robots such as Startship, are also developing.

In Paris, logistics innovation policy is promoted through the establishment of the “Rolling Lab”, a support program and a facility for urban logistics start-ups. But these innovation policies can be failing in several ways. Much of the innovation support is provided

through projects that focus mainly on high-cost demonstrators whose dissemination remains very limited. More fundamentally, cities are seeing the fast train of e-commerce innovations and deliveries pass by without a coordinated response, with each municipality identifying for example its own policy to manage data sharing, or to regulate digital delivery platforms, or to organize the implementation of automatic lockers in public spaces. Few coordinated public policy initiatives are engaged, in areas where market and business strategies are increasingly global.

It should also be noted that technologies for the management of urban logistics using public–private cooperation are still surprisingly limited. Delivery route optimization software do not take into account, for example, access rules or delivery schedules, nor lane closures related to road works. Similarly, municipalities do not have access to company data on urban freight. Taniguchi et al. (2018) propose ways to develop public–private partnerships through an integrated platform for innovative city logistics using big data from private companies and public agencies.

Urban Logistics Planning: A New Field of Policy Intervention

The logistics real estate market is dynamic in large cities and is seeing a diversification of demand in terms of warehouse sizes and formats. Cushman and Wakefield (2017) estimated the demand for e-commerce urban warehouses in Europe for year 2021, to be between 200,000 and 1 million square meters in cities such as Warsaw, Paris, or London. Logistics micro-hubs are also a sought-after commodity in cities. These developments are limited by competition on the urban land market from activities with higher rental yields (offices, housing). This situation favors logistics sprawl, that is the spatial decentralization of logistics buildings from dense areas to distant suburbs (Dablanc and Ross, 2012), which increases the total approach distances to deliver in the city. Decentralized logistics facilities tend to generate more truck-miles as delivery trucks need to cover much longer distances to reach urban destinations. This adds to regional congestion. A regional overview of logistics land uses is therefore needed. So far, few regional master plans set out guidelines for logistics land use and its links to mobility. As a positive example, the Chicago Metropolitan Agency for Planning sets provisions for better accommodating freight land uses in the communities and providing more efficient freight infrastructure (CMAP, 2018). Some issues are often left unresolved such as transit access to logistics developments. An Amazon's giant warehouse near Amiens in France opened in 2017 without anyone having thought of changing the bus traffic plan to site a bus stop near the warehouse.

A potential strategy is the development of logistics parks (sometimes called freight villages), partly through public investment. Some notable examples include *Güterverkehrszentren* (GVZ) at the outskirts of large German cities, or the Raritan Center in New Jersey. These logistics parks commonly include services for logistics companies located on the site, such as surveillance, catering, fueling and cleaning stations for trucks, overnight truck parking, and night accommodation for drivers. Former industrial areas (brownfields) can be used when developing freight villages. However, necessary remediation efforts (e.g., for the removal of polluted soil) should not be too expensive, as programs for logistics facilities development cannot tolerate high land costs.

At a local level, policies for city logistics now include the control of logistics land use through planning, zoning and regulatory provisions. Many cities impose the building of off-street delivery areas in new commercial or industrial developments. The Tokyo off-street parking ordinance compels all department stores, offices or warehouses to provide for loading/unloading facilities when they have a floor area of more than 2000 m². Cities should also be careful in avoiding inadequate regulations in their building and planning codes. Access to underground parking, for example, whether in public parks or in private buildings, can be very difficult for commercial vehicles, even small ones, because of height and size limits. The Chicago Downtown Freight Study of 2008 mentioned this as an important problem for truck drivers and the municipality consequently included recommendations for building provisions.

Requests for proposals have been made in Paris, in France, for converting urban gas stations and car parks into logistics facilities. Some municipalities welcome multistory warehouses. The logistics developer Prologis routinely builds several-story logistics terminals in downtown Tokyo. A three-story warehouse was opened in Seattle in 2017. The acceptance of such projects is increasingly conditioned to environmental criteria and to a careful attention to the integration of buildings into the urban environment. Some cities accept or even promote the development of multiactivity buildings, with logistics on street levels and other activities on the upper levels. One example is the Chapelle “logistics hotel” (a logistics hotel combines multiple levels and mixed uses) that was opened in Paris in 2018 (CITYLAB, 2018). Built on four levels, it combines an intermodal facility, a warehouse, public sports facilities, an urban farm, offices and a data center. The development of “urban consolidation centers” (UCCs) has often been identified as an interesting strategy to reduce urban freight impacts. These facilities provide a service of bundled and coordinated deliveries, often requiring public subsidies. Up to 200 such terminals existed in European cities in the 1990–2000s. However, due to operating costs, most of them closed down when municipalities could no longer subsidize them. Today, a few UCCs are operating, mostly in medium-size cities: Bristol in the U.K., Modena, Padua and other Italian cities, La Rochelle in France, Yokohama in Japan, and the city center of Gothenburg in Sweden (Figs. 2 and 3).

Curbside Management: A New Sharing of Public Space

Freight operators need good access to dedicated loading and unloading areas, be they public or private, on-street or off-street. The lack of sufficient delivery areas transfers delivery operations on traffic lanes (double-parking) or sidewalks, and leads to congestion

Figure 2 A micro-hub for FedEx by the Seine river in Paris, France.

Figure 3 Warehouse development in suburban areas, Atlanta, United States, 2018.

and traffic accidents. In busy urban areas and city centers, adequate on-street loading and unloading bays must be identified and their use must be better controlled. However, cities generally implement very local solutions for managing delivery vehicles on the road, without common operating procedures emerging. Municipalities have a rather case-by-case response to requests from carriers and retailers. The first national technical guideline on the subject in France was only published in 2013, much later than guidelines for bus stops or bike lanes for example. The City of Paris has organized its own procedures for the design of loading bays: a minimum of one every 100 m in the city streets is required, and a loading bay cannot be less than 10 m long to allow drivers to use a tailgate lift. In London and Paris, bus lanes are open to delivery trucks, but while in Paris trucks can enter them to deliver on the “Lincolns” (delivery areas set up half on the sidewalk and half on a protected bus lane), in London trucks can drive on the “bus and lorry lanes” but not load or unload from there. European municipalities differ considerably in the way they accept new delivery equipment in public spaces, such as automatic parcel lockers (widely refused in France, accepted in Germany) or parking permits for trailers serving as a temporary depot from which cargobikes or delivery droids supply neighborhoods (promoted in Belgium cities, not so much in other cities).

Time sharing is a good way to improve street parking capacity for trucks and vans. On Barcelona’s main boulevards, the two lateral lanes are dedicated to traffic during peak hours, deliveries during off peak hours, and residential parking during the night. The city is also renowned for its dedicated mobility motor squad consisting of 300 agents circulating with a motorbike and controlling all on-street parking activities including loading/unloading. This has prevented illegal long-term parking and made these zones always available to delivery truck drivers. A more ‘intelligent’ management of delivery areas is emerging. However, there are more projects than achievements. In Barcelona, delivery drivers have to register on a smartphone application (AreaDUM) with their vehicle registration number. Once they arrive at the delivery bay, the application identifies their location, which they must confirm. A 30-min window then opens to carry out the delivery operation. The urban planning concept of “complete streets” still needs to include freight and delivery activities. [Conway et al. \(2019\)](#) provides the first comprehensive strategy for a better integration of truck parking and loading infrastructure in street design and management. Diagrams and photos are provided for a more efficient design of street

Figure 4 An electric quadricycle for deliveries, Amsterdam, The Netherlands.

space accommodating multiple users, including commercial vehicles. In Seattle, the Urban Freight Lab looks at the “final 50 feet” of freight activities in cities, testing solutions such as new design for loading bays or common carrier delivery lockers (Urban Freight Lab, 2018).

De-Polluting Commercial Vehicles in Cities

Municipal authorities are seeking to improve the average condition of commercial vehicles’ urban fleets, which are much older than passenger cars and long distance freight vehicles. In the current state of the market and prices, a substantial increase in the fleet of clean vehicles, particularly electric delivery vehicles, cannot be expected without financial support for small operators, which is what many cities are doing, often in addition to national support. Oslo, in Norway, is the city with the widest range of financial and regulatory support for electric vehicles, but the market share of electric vehicles for commercial vehicles is only 2% of new vehicles, whereas it is now more than 50% for private cars: tax aid plays less of a role for commercial vehicles, which are already partially exempt. A detailed analysis taking into account the operating constraints of delivery companies, the continuous improvement of battery capacity and the maintenance of overall public subsidies for clean vehicles estimates the market share of electric delivery vehicles in French cities at only 13% in 2032 (Camilleri, 2018). Subsidies and charging stations are the two main challenges for policies targeting cleaner commercial vehicles in cities. The mayor of London introduced in 2020 grants of around €17,700 for each truck up to three trucks for operators in need of updating their fleets. A van scrappage scheme grant will be doubled. The question of installing charging stations, especially fast charging ones, on public roads is key but many municipalities are hesitant because of the cost of supportive policies. Avoiding costly investments, particularly municipal investments, could be justified in view of the promise made by car manufacturers of the introduction of vehicles with batteries allowing a driving range of more than 200 km and which have a higher load capacity than today’s vehicles. But in the meanwhile, conversion to electric vans is too slow, especially in tense markets such as New York, Los Angeles, Paris or London, in need of fast charging stations. According to the Rocky Mountain Institute, Shenzhen (China) is amongst the cities in the world with the highest number of electric delivery vans (70,000 by the end of 2019). This is due to two specific municipal policies: exemptions from freight vehicles’ time restriction; and strong municipal policy for the implementation of charging stations (Crow et al., 2019) (Fig. 4).

Data Collection, Data Analytics, Urban Freight Modeling, Policy Assessment: Huge Gaps in Policies

A successful urban freight policy includes good knowledge of logistics activities and the use of efficient tools of data collection, processing and modeling, and policy assessment. Urban freight indicators should be collected and examined overtime, in order for cities to understand major trends in commercial vehicle flows, consumer demands in online retail, innovations in logistics services, and impact of policies. However, data collection efforts in urban goods movements are broadly insufficient, whether for B2B data (business-to-business, freight trips made to or from businesses in cities) or for B2C or C2C data (Business to Consumer, Consumer to Consumer, resulting from online transactions). Specific urban freight surveys, of the type of household travel surveys made for passenger transportation, are expensive and municipalities or higher levels of governments are reluctant to pay for them. Examples of comprehensive efforts include: the Freturb urban freight model in France (Toilier et al., 2018), and production from the Center of Excellence for Sustainable Urban Freight Systems (Rensselaer Polytechnic Institute). New sources of data are explored, requiring local governments to partner with freight operators and other data owning business stakeholders such as e-retailers or

telecommunication operators. Anonymized big data from urban freight operations (private and public) are collected and processed by a neutral third party such as an academic center, then returned to municipalities and operators as user-friendly management/prediction tools. Projects to achieve such comprehensive tools are on their way but none is complete yet. In the shorter term, progress is expected on the use of policy assessment indicators by cities, such as the ones provided by Van Rooijen et al. (2008) or Holguin-Veras et al. (2018).

Conclusion

With the rapid changes in patterns of consumption, production and distribution, many of them accelerated by the recent covid pandemic, urban freight challenges have increased in cities worldwide and have become a topic for policy. Governments at various levels have a wide range of policy tools at their disposal to act on urban freight. Paradoxically however, they do not implement them to any great extent, and some areas such as the collection of data and use of urban freight models, training and career development in urban distribution and warehousing, or the reduction in urban freight carbon emissions, are not yet strong targets of policy. There is a lack of a global urban policy framework conducive to sustainable logistics. Basic targets are not yet achieved, such as the elimination of polluting commercial vehicles in cities, or enforcement of labor/market laws toward small transportation companies or digital workers operating illegally. The result is that the most innovative and sustainable freight operators find it difficult to impose themselves. There are many examples of progress made: low emission zones, improved curbside design for loading/unloading bays, the use of Intelligent Transport Systems (ITS) in many of the private, public and public-private city logistics activities, a better consideration of urban warehouses in the planning process, for example. But a more global approach to urban freight policy, on a metropolitan scale at least, with links to concepts such as circular economy, smart mobility, energy transition, has yet to be implemented in many cities around the world.

Introduction

Regional transport planning, which is undertaken at a subnational level and primarily influenced by changing institutional structure and political discourse, is one of the most elusive concepts of transport planning. A need for planning at a regional level was recognized in the 1920s in advanced western countries mainly on two inter-related grounds; namely, the interdependence of several municipalities and significant issues relating to rapid metropolitan growth beyond individual administrative boundaries, and the growing regional inequality between mega city-regions and other regions of the country. However, the role of transport in addressing these problems has been controversial. On the one hand, it is a challenge to define a suitable regional scope with an acceptable form of governance that can deal with common transport needs more effectively. On the other hand, an economic rationale tends to determine regional transport planning rather than equity concerns. This article aims to discuss the regional concept of transport planning and examine key themes underpinning the regional transport planning practice by drawing on the extensive experiences based in the USA, including delimitation, integrated transport planning, planning techniques and goals, and institutional reform and governance.

The Regional Concept of Transport Planning

Defining a Region

A “region” is an intermediate level between the basic local unit and the state (Dickinson, 1964). However, the definition of a region is slippery by nature. Keating (1998) provides three perspectives to defining a region; namely, administrative, economic, and cultural, arguing that these concepts could coincide and may conflict with one another. First, from an organizational viewpoint, a region is, ideally, a subnation division through formal government legislation. However, the extent to which regional institutions can exert their political power varies with nations. Second, from the economic perspective, a functional city region, generally beyond the fixed administrative boundary, reflects the dynamism and close interdependence among a network of cities based on their functional attributes, the travel to work pattern, and market linkages. Third, from a cultural angle, regions can be defined by history, language, and a sense of regional identity. The geographical scale of a cultural region may vary dramatically.

Origin of Regional Problems and Regional Policy

Hall (2002) distinguishes two scales of planning: the regional/local scale (city-region) and the national/regional scale to address regional problems. The first scale of regional planning reflects problem-oriented thinking. Patrick Geddes’ *Cities in Evolution* (1915) and Lewis Mumford’s *Culture of Cities* (1938) well capture a need for city-regional planning to tackle issues such as sanitation, transport and governance for an area of everyday living. The larger the size of urban expansion, the more urgent the demand for solving city regional problems. Similarly, Wallis (1994a) identifies three stages of social and economic restructuring in metropolitan areas in the USA, which underlie three waves of regionalism reform. The first wave corresponds with the growth of monocentric city-regions during the mass manufacturing and industrialization process. The second wave results in poly-centric metropolitan regions, where suburbs are adequate substitutes for central cities in production and distribution. The third wave attempts to address city-regional development in the globalised world, where a postindustrial society has a much higher proportion in services than manufacturing.

The second scale of regional planning—national/regional planning is different, but relevant to the first scale of city-regional planning, addressing the inequality of regional development. Issues relating to regional inequality hit hard in postindustrial western countries, while approaches to regionalization varied widely between different countries. France is especially renowned for its intervention in tackling excessive concentration of development around Paris (Dickinson, 1964). Before regional divisions emerged, an administrative tier named “*department*” was insufficient for dealing with regional issues. In the mid-1950s, programmed regions were assigned in the national plan and evolved in status by gaining legitimate responsibilities from 1982 onwards.

The Role of Transport in Regional Development

Transport plays essential roles in growth and development. Friedmann and Stuckey (1973) identified the role of transport in three aspects. First, transport can facilitate economic growth in response to demand. Second, transport drives development through a supply strategy that provides transport services ahead of demand, often attempting to solve problems encountered by lagging regions. In this regard, transport is decisive in reshaping spatial relationships; for example, the location of economic activities, a pattern of settlements, and social interactions. The co-evolution of transport and urban structure is exemplary. Third, apart from the connective functions, transport could be a divisive force to destroy a community through severance, which is evident in the environmentalist movement reacting to motorway construction.

Regional transport planning originates from a political view that in addressing emerging regional problems; for example, disparate development between regions. The under-developed regions which could not be left to experience market failure and thus needed to be tackled through regional policy and regional economic planning, in which transport plays a critical part. Oettle (1979) argues that public transport services should provide freedom of movement for underdeveloped regions.

However, the role of transport in addressing regional problems is often contested, in particular concerning rebalancing the effects of transport in lagging regions. Voigt (1979) argues that the instrumental character of transport in regional policy for addressing uneven regional development depends on the intended use of four spatially differentiated socio-economic structuring effects; namely, investment, income, capacity, and degree of freedom for a competitive strategy. Meanwhile, he also highlights the limitations of a transport policy as an instrument of regional policy without a coordinated package of measures that include both transport and nontransport policy areas.

National political economies in differing political settings and broader contexts play vital roles in accounting for varied intervention in transport systems to address regional problems. Bonnafous (1979) highlights that in France and most western European countries the notion of optimal allocation of resources was dominated by economic calculation and justified by profitability, meaning that infrastructure was only developed when an existing provision was demonstrably overloaded and holding back accumulation. However, in the 1970s, restructuring of space received unanimous priority for balancing regional development and the indirect effects of infrastructure. “The transport policy is then no longer assimilated to an optimum sectoral policy but is to be included in a much larger framework” (ibid., p.48). He stresses “transport can only be an auxiliary of a regional policy which employs all the other instruments of planning. None the less, good use of this auxiliary is no more evident” (ibid., p.56).

The UK government’s dominant view of value-for-money in transport investment results in funding resources concentrated in thriving growth places rather than lagging regions (Marshall, 2011). History has shown that transport planning at the regional level was promoted most strongly during 1997 and 2010, although the overall result might not have been as significant as expected. Since the abolishment of regional government in 2010, the England regions outside London struggled to exert proper regional transport planning, and the focus has been placed around city-regional transport planning efforts around large regional cities. Instead, regional transport planning has been implemented more effectively in Greater London, Scotland, and Northern Ireland where devolved power was secured at the regional level.

Blonk (1979) concluded that transport is a catalytic force, both an agent vital for industrial growth and an agent of decline where economic resources, conditions and human endeavor are insufficient to meet the competition of outside areas. Transport plans should support government policy; for example, land use, regional development, and urban policy. Timely coordination and regular reviews and updates of transport policy with regional development and land use planning are essential. Transport modes should be complementary to each other. Integrated transport models should reflect dynamic spatial patterns.

Key Themes of Implementation of Regional Transport Planning

Delimitation

Although the need for regionalization in the field of transport planning is widely acknowledged, defining a boundary for a regional concept of transport planning is contested. There are two available options. First, one can be mutually exclusive in dividing the nation into several regions; the second is to overlap with existing institutions. Which option to choose varies with different countries? Both options exist in the regionalization of France. However, in the USA, an exhaustive and permanent regionalization for transport planning purposes would not seem desirable (DeSalvo, 1973). Referring to Friedmann (1956) who suggests that in any developed economy basic spatial patterns can be expressed between (1) a central city and its surrounding region and (2) one city region and another, Friedmann and Stuckey (1973) argue that city and region can be accordingly treated “as a unit that is characterized by a tight pattern of functional interdependencies and articulated by a system of transport and communication facilities” (p.143). What should be considered when dividing workable transport regions? Should the boundary be identical for

different target groups; for example, freight and passengers and other transport modes? They summarize four approaches proposed by various scholars for delimitation; namely, (1) daily newspaper circulation and a Federal Reserve District boundary; (2) a standard metropolitan statistical area; that is, functional economic areas equivalent to the labor market of a city, based on commuter data; (3) a daily urban area (a radius of approximately 80 miles around urban centers; (4) an urban field, based on the metropolitan core areas and the inter-metropolitan periphery. Since the interaction of activities will determine the form of the region, they argue a region is primarily a taxonomical concept and should be delineated by specific activities on an ad-hoc basis. For instance, state-level intermodal coordination, an inter-state urban corridor, can avoid designating particular transport regions. Under such thinking, the fourth concept, which includes peripheries, literally tends to be ignored and become a remaining issue left by emphasizing metropolitan-centered regions, because those peripheral areas could not demonstrate their relationship with the metropolitan cores sufficiently (*ibid.*).

Integrated Transport Planning

As discussed earlier, the role of transport should be part of an overall regional policy, and the integrated planning process of transport and nontransport measures cannot be overstated. [Klaassen and Bourdrez \(1979\)](#) call for comprehensive transport planning, which should consider simultaneous horizontal and vertical integration. They argue that planning at the regional level should play a strategic role in the reconciliation of the top-down and bottom-up approaches to the entire planning process ([Klaassen and Paelinck, 1974](#)).

Horizontal integration denotes that transport planning should link with plans and development in various areas, including size, growth and composition of the population, education systems, labor market, economic activities, energy demand and supply, transport infrastructure, social infrastructure, living conditions and recreation, the environment and the ecological system, and land use possibilities ([Klaassen and Bourdrez, 1979](#)).

Vertical integration at the regional level implies that transport planning should consider transport plans at both higher and lower levels. Issues of vertical integration can be approached from two directions, bottom upwards and top downwards. Although local knowledge and needs are better grasped from the bottom upwards, difficulties may lie in lack of power at the regional level to coordinate the local conditions. Moreover, adding up the local needs does not necessarily lead to an optimal situation for all. From the top downwards, the issues include bureaucracy, inflexibility, insufficient local knowledge, and fewer practical solutions (*ibid.*).

[Klaassen and Bourdrez \(1979\)](#) argue that reform of local government responsibilities in the fields of traffic and transport might be a necessary precondition for establishing an effective and concerted planning process (*ibid.*, p.71). The aspects of reform include

1. societal integration
2. economic integration
3. administrative integration
4. integration over time
5. integration of modes of transport
6. integration of public and private passenger transport and of goods transport
7. integration of traffic plans and parking plans
8. spatial integration: coordination of inter-city traffic and urban traffic, long-distance rail transport, the primary road network, and the primary-secondary, tertiary, and urban road system

Planning Techniques and Goals

Development of new computer modeling and systems analysis techniques boosted regional transport studies in the late 1950s and 1960s, setting a substantial precedent for technical analysis at the regional level ([Goldman and Deakin, 2000:48](#); [Wallis, 1994a](#)). However, the capacity of transport modeling in reflecting dynamic regional development patterns is questionable. [Hall \(1967\)](#) argues that problems of a systematic methodology developed for metropolitan area transport studies lie in predicting land uses and the underlying social patterns, arguing that it is unlikely to generate satisfactory interpretation for the modeling work. Close communications among experts in different aspects of urban growth and change could improve the level of performance. Similarly, [Klaassen and Bourdrez \(1979\)](#) argue that conventional transport models assume traffic flows could develop exogenously, failing to consider reality.

Techniques used in the regional transport planning process have evolved in response to changing goals. In the early days, congestion issues derived from road building were addressed when efficiency was the primary concern. Cost-benefit analysis (CBA) is widely used to determine value-for-money through monetized calculation while failing to effectively take into account a multidimensional and broader range of goals in regional transport planning ([Aberle, 1979](#)). In the US, both the 20-year long-term plan and the 3-year shorter-term transport improvement program consider seven critical criteria, including economic vitality, safety and security, accessibility and mobility, quality of life (including environment and energy conservation), integration and connectivity, system management and operation, and preservation of existing systems ([McDowell, 1999, 10](#), cited in [Wolf and Fenwick, 2003](#)). A planning scheme justified on benefit-cost grounds could make the rich richer and the poor poorer, failing to address the inclusive and redistributive issues.

There is a general tendency to embrace new tools for assessing a broadened range of goals and strategies, including an increased emphasis on public involvement in regional transport planning. [Handy \(2008\)](#) develops a framework of performance measures,

arguing regional transport planning agencies have worked to revise planning processes and create new tools. She stresses the significant challenges metropolitan planning organizations face in response to a new transportation planning philosophy (*ibid.*).

Although there is a general acknowledgment of a broader range of goals, some equity issues are inherited and structural. Luna (2014) demonstrates that preexisting and persistent residential segregation results in procedural inequity for representation and participation in transport planning.

Institutional Reform and Governance

Institutional reform and governance contribute to effective metropolitan/regional transport planning with varied effects in different countries. There is a consensus that institutional planning is indispensable, including the organization of decision-making and distribution of power among different levels of government. Klaassen and Bourdrez (1979) emphasize that planners should consider government structure, the administrative system, the legal and fiscal framework, and the financial possibilities. Various regional structures, with or without legal status, have been created to address issues through avenues of actions (Dickinson, 1964). However, institutional reform does not necessarily mean a regional tier is required. DeSalvo (1973) argues that addressing regional transport problems should not mean they have to be dealt with by regional authorities.

In the context of the USA, supporters of metropolitan/regional transport planning agree that there are important mechanisms for ensuring local control over federal funding and that they deserve more broad authority to implement the plans they create. At the same time, critics have argued that they usurp legitimate functions of state governments and constitute an unnecessary layer of bureaucracy (Solof, 1998). Public choice theorists argue that “a public economy composed of multiple jurisdictions is likely to be more efficient and responsive than a public economy organized as a single, area-wide monopoly” (Bish and Ostrom, 1973, p.2). The idea of choice is constructed in a competitive environment where local governments are encouraged to facilitate, and individual households and businesses are free to make decisions about where they would like to be located. In this line, because regions are treated effectively as markets, and individual municipalities behave as firms, the boundaries of a region will vary according to the needs created for specific services. However, in this dominant perspective of competition, social welfare programs are not encouraged as taxes will increase costs. Consequently, the responsibility for the redistributive program might not be undertaken (Wallis, 1994a).

Institutional reform

The following paragraphs draw on the extensive experiences in the USA where regional transport planning practice has progressively evolved from the 1960s to illustrate how institutional reform and governance contribute to regional transport planning beyond an unnecessary layer of bureaucracy. Under the 1962 Federal-Aid Highway Act, metropolitan areas with a population of over 500,000 are required to establish a “continuing, cooperative, coordinated” planning process by representatives of local governments or forming metropolitan planning organizations (MPO) to develop regional transport plans.

MPO is defined as “a core area containing a large population nucleus, together with adjacent communities having a high degree of economic and social integration with that core” (the US Census Bureau cited in Solof, 1998). Some state laws create regional transport planning authorities for developing regional transport plans. For instance, the Puget Sound Regional Council is an MPO by the federal law as well as a regional transportation authority by the state law. MPO have been evolved with various forms. For instance, the planning responsibility of MPOs has been further strengthened over the years by the Intermodal Transportation Efficiency Act (1991) and the Transportation Efficiency Act for the 21st Century (1998) where both the 20-year long-term plan and the 3-year shorter-term transport improvement plan are required under the leadership of MPOs. The two plans are not just a wish list but are an identified list with revenue sources. In order to have a right balance in executing the federal mandates and seizing federal funding opportunities as well as being controlled by the state officials in matching funds, MPOs must “both coordinate local interests and achieve a workable agreement on the regional plan, and cooperate with the state highway department to have regional projects funded” (Goldman and Deakin, 2000:49).

The origin and evolution of MPO reform in regional transport planning reflects that the effectiveness of new institutional reform depends on both statutory capacity and internal capability. Before the creation of MPO, restructuring, for example, political unification is regarded as a means of securing comprehensive regional governance, such as annexation in various forms, which were achieved mainly through “legislation actions without resources to a local referendum” and subject to “strenuous objections of suburban municipalities” (Wallis, 1994a:161). The introduction of MPOs was characterized with procedural reforms designed to improve program coordination and comprehensive planning. In the first three decades following its introduction, MPOs gained modest responsibilities, and the basic framework remained intact: a relatively weak regional institution representing the interests of local agencies and often dominated by the State Department of Transport (DOT) (*ibid.*). In the 1990s, MPOs were empowered to be the leading agency in the planning process (including representatives of local governments, operators of major transport modes, and appropriate state officials) and to control some categories of federal planning funds. These new responsibilities would be carried out in partnership with state agencies and a variety of public and private interest groups to enable a consensus-based process for a vision of the region’s future and improving institutional capacity for sustained implementation was (Wallis, 1994b).

Institutional governance

In addition, to institutional reform of empowerment to the metropolitan planning organization, it is crucial to overcome the difficulties of institutional governance in coordinating two distinct and separate policy arenas, namely transport and land use planning in regional transport planning. Goldman and Deakin (2000) identify five types of partnership in order of increasing levels of interaction, shared responsibility, and role equality; namely, consultation, coordination, cooperation, consensus building, and

collaboration. Most MPO activities belong to the first three types of partnership, and it is evident that “a stronger MPO role has not been universally accepted and, in several regions, key actors, public and private, remain opposed to a strong MPO role” (p.70). However, they argue that lower-level partnership could still evolve to a higher-level collaboration, although this is not guaranteed. To devise useful models for progressive practice, they call for research into social learning aspects of partnership development and evolution of regional institutions.

Three factors appear to make metropolitan planning organizations more likely to engage in these coordination practices, namely environmental pressures and contemporary trends, a right balance of land use and transport-related representatives by state laws, and local capacity (e.g., actions by MPO staff and practical leaders) (Wolf and Fenwick, 2003).

Firstly, Federal programs in line with contemporary trends such as a Liveable Communities Initiative have encouraged linking transport and land use transport. However, land-use planning is not regarded as one of the seven factors in the federal mandate. Similarly, considerable progress in integrating transport and other policy areas has been made in various popular planning models, such as multimodal transport planning, station area development (transit-oriented development), in-fill development, and urban growth boundaries. One can imagine that the latest decarbonization plan will play a similar role in facilitating integration further.

Second, state laws that instruct a good balance of both land use and transport-related representatives on metropolitan planning organization boards are instrumental, but local practice varies. Under the new legislation for MPO responsibility, Goldman and Deakin (2000) find that geography-based representation dominates MPO boards, providing limited roles in which transport operators could become involved. For instance, despite these agencies being members of MPOs, they are often excluded from voting. Issues relating to lack of representation on MPO boards appear to be a significant obstacle to their ability to gain strong powers for regional governance. Seattle’s Metropolitan Municipal Council dissolved because its governance structure violated the constitutional principle of one person, one vote (Wallis, 1994a; cited in Goldman and Deakin, 2000).

Third, local capacity plays a role in the variation of coordinating land use and transport among MPOs. Goetz et al. (2002) argue that MPOs vary considerably in their ability to coordinate regional transport planning. Similarly, Wolf and Fenwick (2003) find there is a certain degree of coordination and a limited number of MPOs that lack coordination. Their analysis found three levels of coordination in practice. The first level involves some coordination, but these activities are not significant efforts because there is fear that the coordination would force local concessions for regional land use, and this would establish precedents for plans. The second level of coordination is bottom-up and heavily driven by local policy boards. The third level refers to those extensively and comprehensively coordinating transport and land use planning. Widely praised good models include Portland (Oregon), Minneapolis, St. Paul, and Seattle with the power given by state legislation to involve in coordination.

Wolf and Fenwick (2003) suggest four general strategies for coordinating transport and land use planning: namely, leveraging technical capacity (transport modeling, air quality conformity analyses, GIS services, and scenario analysis), initiating special projects (driven by fund programs and project advocates including MPO staff, policy leaders, and the community), developing ways to educate and involve the community (a strong and credible citizens’ advisory committee is commonly formed and charged with issues of congestion, growth and land use), and tying land-use issues to planning processes (land use considerations are included in either long-range plans or a specially focused corridor plan. In either case, the extent and significance of this land-use component cannot be readily determined because there are good intentions rather than actual plans for implementation) (ibid., 127).

Summing Up

This article examines the nature and development of regional transport planning, mainly drawing on the experience in the USA, which has established and progressively evolved its regional transport planning practice from the 1960s. Although different countries have different background and trajectory and political economy, this article discusses four critical themes including delimitation, integrated transport planning, planning techniques and goals, and institutional reform and governance, which are pivotal in implementing regional transport planning per se. Transport planning goals have been widened over time to embrace multiple-criteria objectives, including equity and inequality issue, thus a holistic and inclusive approach to integrating transport planning. Development should be instrumental in achieving effective regional transport planning and implementation in the dynamic and widening metropolitan and regional development process, including effective leadership, staff competence and credibility, development of a regional ethos, meaningful public involvement, and a cooperative relationship with the lower and higher levels of transport authorities, streamlined and efficient processes, integrated land-use planning, and accountability.

Definition of Project Finance

There are three possible financing approaches for a project: (1) corporate finance, based on the creditworthiness of the company, (2) object finance, based on the value of the asset, and (3) project finance (PF), used to finance capital-intensive long-term initiatives generating a predictable cash flow, such as the case for transport infrastructure. When the public sector (state government, local government, or transit agency) is the project initiator, PF can be referred to as public–private partnership (PPP or 3P). PF is used for self-contained projects, having a finite life, with high debt to equity ratio, and no or limited guarantees provided by the investors. The future cash flow is used for interest and debt repayment to investors and lenders (Daube et al., 2008).

Within the context of PF, a new company is specifically created for fundraising and the Project Company or Special Purpose Vehicle (SPV) carries out the project. A number of entities, each with a specific role (Fig. 1), are part of project. These are:

- the project company, characterized by an equity and debt structure enabling it to manage the cash flow generated by the project;
- the public sector, generally the project initiator, providing guarantees and acting as project sponsor;
- Lenders, providing debt and allowing the diversification of the project risks across different banks;
- Banks, acting as mandated lead arrangers, participants providing the funds, and advisors and consultants to the sponsors;
- the project sponsors. They are either institutional investors (private equity companies, infrastructure funds, insurance companies, pension funds, government agencies, investment banks, regional development banks) and/or companies (construction companies, suppliers, and operators) investing their capital in exchange for an equity stake in the project;
- Contractors, carrying out planning, design, and construction of the project;
- Input suppliers, providing materials and components of the infrastructure;
- Operators, responsible for maintaining, and operating the infrastructure after completion;
- Insurance companies, taking care of risk insurances;
- Consultants, providing due diligence and help selecting the bank consortium and defining the project structure (Bengtsson, 2019);
- The offtaker, that is, the party buying the product or service that the project produces.

PF is implemented via contractual agreements aimed at specifying the operating and revenue risks and at allocating them among all the parties involved in the project (Estache et al., 2008). The concession agreements assign the company in charge for developing the project the right to construct the infrastructure and to earn revenues by either charging an operator using the infrastructure (e.g., multimodal operators or freight forwarders using logistic platforms or intermodal centers), or by providing a service to the general public (e.g., toll roads). Several types of concession agreements are possible. For transport infrastructures, the most commonly used type is the build–operate–transfer, according to which the project company has only the right to operate the infrastructure and to earn revenues within a finite period, but it does not own the infrastructure which, in fact, belongs to the public sector. A similar and frequently used agreement is the build–transfer–operate. In this case, the ownership of the infrastructure is taken over by the public sector only after the completion of the project. Other types of agreements include leasing, joint ventures, contracting out, design–bid–build, design–build, design–build–operate, design–build–finance–operate, and pure operation and maintenance (Evenhuis and Vickerman, 2010; Kumari and Sharma, 2017).

Benefits and Risk

PF provides a large set of benefits both to investors and third parties. It involves, however, also risks. Along the lines suggested by Yescombe (2013), we divide PF benefits into two groups: the benefits to investors and the benefits to third parties. The former include:

- High leverage. It is one major reason for using project finance. Long-term investments do not offer a high return: high leverage improves the return for an investor.

Figure 1 Stakeholders involved in PF. Source: Adapted from Yescombe (2013, p. 8).

- Tax benefits. If interest is tax deductible and dividends to shareholders are not, debt becomes even cheaper than equity, and hence encourages high leverage.
- Off-balance-sheet financing. If the investor has to raise the debt and then inject it into the project, this appears on the investor's balance sheet. On the contrary, a project finance structure may allow the investor to keep the debt off the consolidated balance sheet. This takes place more easily when the investor is a minority shareholder in the project.
- Risk limitation. An investor raising funds through PF does not normally guarantee the repayment of the debt: the risk is therefore limited to the amount of the equity investment.
- Risk spreading/joint ventures. When a project is too large for one investor, others may be brought in to share the risk in a joint-venture project company. This enables the risk to be spread among investors.
- Long-term finance. Project finance loans typically have a longer term than corporate finance.
- Enhanced credit. If the offtaker has a better credit standing than the equity investor, this may enable debt to be raised on better terms.

The benefits to third parties (offtaker or end users of the project) are the following:

- Lower product/service price: when a high level of debt is possible, the price of the product/service will be lower.
- Additional investment in public infrastructure: PF provides funding for additional investment in infrastructure that the public sector might otherwise not be able to undertake because of economic or financial constraints on the public-sector investment budget.
- Risk transfer: a PF contract transfers risks (e.g., project cost overruns) from the public to the private sector.
- Lower project costs: an important characteristic of PF is that the private sector might build and run such investments more cost-effectively than the public sector, even after allowing for the higher costs of project finance compared to public-sector finance. Such a property is dependent on:
 - the general tendency of the public sector to "over-engineer" or "gold-plate" projects;
 - greater private-sector expertise in controlling and managing the project construction and operation, given the private sector ability to offer incentives to managers;
 - the private sector being willing to assume the risk of construction and operation cost overruns;

- a “whole life” management approach rather than ad hoc arrangements for maintenance dependent on the availability of further public-sector funding;
- the absence of the “deal creep” phenomenon (i.e., increases in costs during the construction and operation phase).
- Third-party due diligence: benefits from independent due diligence and control of the project exercised by lenders, who want to ensure that all obligations are fulfilled and risks are adequately dealt with.
- Transparency: since a PF is self-contained, the true costs of the product or service can more easily be measured and monitored.
- Additional inward investments: when successful PF might open up new opportunities for infrastructure investments and can act as a showcase to promote further investments in the wider economy.
- Technology transfer: for developing countries, PF provides a way of producing market-based investments in infrastructures for which the local economy may have neither the resources nor the skills.

PF entails also several risks. [Yescombe \(2013\)](#) groups them into three main categories. First, there are commercial risks inherent to the project itself or to the market in which it operates. Second, the macro-economic risks (financial risks) related to external economic effects (e.g., inflation, interest rates, and currency exchange rates), and lastly, the political risks (country risks) related to the effects of government action (change of laws, contract disputes, expropriation) or political events such as war and civil disturbance, especially in case of cross-border financing or investments. Commercial risks comprise of the following:

- commercial viability risk: the overall financial and economic sustainability of the project;
- on time and on budget completion risks;
- environmental risks during construction or operation;
- operating risks related to achieving the planned costs and performance levels;
- revenue risks related to achieving the expected revenues;
- input supply risks related to acquiring materials or other inputs at the projected costs;
- contract mismatch risks related to the co-ordination of the project contracts;
- sponsor support risk: lack of support from the sponsors.

The core role of PF is to assess, manage, and properly insure against such risks. Risk analysis should be based on due-diligence, risk identification and quantification, and risk allocation through contracts including the lenders.

The risks differ by project phase. Construction projects typically have four distinct phases: planning, construction, operation, and decommissioning. A typical risk in the planning phase is the design error. In the construction phase the typical risk is cost overrun, while in the operating phase there is the risk that the demand for the asset is lower than expected (for further reading, see [Macário et al., 2015](#) for the Portuguese experience with PPP).

PF for Transport Projects

PF for Transport Projects in Theory

Several projects can be realized with PF including ([Weber et al., 2016](#)):

- transport assets (roads, railways, bridges, tunnels, ports, airports, inland waterways, tramways, subways, intermodal centers, and logistic platforms);
- public utilities (oil and gas networks, electricity transmission, allocation and distribution networks, water supply, treatment, disposal systems and waste disposal facilities, telephone and communication networks);
- natural resources projects (oil field or mining, renewable energy projects such as wind and solar parks);
- public buildings (schools, hospitals, administrative buildings, and social housing).

The projects financed via PF are construction projects in which an asset is either built (greenfield projects) or improved, upgraded, or expanded (brownfield projects) ([Rossi and Stepic, 2015](#)).

Infrastructure projects are particularly challenging since the project’s net present value (NPV) can be negative, making investments unattractive for the private sector. However, indirect benefits to communities may make them worthwhile ([Ehlers, 2014](#)). The cash flow time profile might also be unattractive, with high upfront investments and cash flows that cover costs occurring only in the last project phase ([Ehlers, 2014](#); [Sorge, 2004](#)). Finally, infrastructure projects are very complex since a large number of parties might be involved ([Ehlers, 2014](#); [Sorge, 2004](#)), and their success depends on the joint effort of all parties. Coordination problems, conflicts of interest, and free-riding can lead to project failure ([Sorge, 2004](#)). Infrastructure investments, however, can be financially attractive because often these projects offer long-term predictable and stable cash flows that allow the projects to have a high leverage ([Rossi and Stepic, 2015](#)). Additionally, some infrastructure projects protect against inflation, as payments, such as tolls, are connected to inflation security due to PPP arrangements ([Rossi and Stepic, 2015](#); [Weber et al., 2016](#)).

Transport projects are public goods whose consumption is nonexcludable and nonrival, preventing private sector from directly financing them. Moreover, they are strategic assets that critically determine the economic and social development of a country ([Aschauer, 1989](#); [Button, 1998](#); [Calderon and Servén, 2004](#)). They generate both positive (stimulating economic growth and increasing productivity) and negative (environmental impact, pollution, congestion, and visual impact) externalities, which are not accounted for by private investors when evaluating their financial returns. Finally, they give rise to natural monopolies or

oligopolies whose technical and operational standards are regulated by public authorities. For these reasons, governments have traditionally financed their construction, via either public-sector debts or using revenues collected from taxpayers. Moreover, they require large sums for their maintenance (Meunier and Quinet, 2010), but over time the availability of public funds in many countries has reduced.

PF for Transport Projects in Practice

This section provides a review of some country experiences with PF for transport projects. The focus is on the United States, Australia, and European countries.

In the United States, the federal surface transport programs are mostly funded through taxes on motor fuels that are deposited in the highway trust fund (Kirk and Mallett, 2013). The tax rates (in terms of cents per gallon), however, have not been increased since 1993. Prior to the 2007 recession, annual increases in driving and fuel use were sufficient to keep revenues rising steadily. This is no longer the case. Increases in fuel economy standards and the switch to electrification are likely to reduce motor fuel consumption and, hence, tax revenue in the years ahead. The US Congress has financed the federal surface transport program by supplementing fuel tax revenues with transfers from the US Treasury general fund, but it did not address concerns about the funding of surface transport programs over the longer term. Consequently, there has been a growing interest in improving transport infrastructure with private and non-grant funding sources, such as tolls, PPPs, and federal loan programs, but many projects may not be well-suited to alternative financing. Typically, the “public” in PPPs refers to a state government, local government, or transit agency. Since the United States has a comprehensive and relatively mature transport infrastructure network, about 85% of the total public capital investment in transport system in recent years is directed toward maintaining and repairing it, and not toward constructing new facilities or adding capacity to existing ones. Two decades of experience have shown that private investment is attracted to large, complex and expensive transport projects that add new capacity to the US system and can be supported by a revenue stream, usually through tolling. Thus, the overall market share for PPP projects in the overall US transport construction market has been—and likely will remain according to Kirk and Mallett (2013)—fairly small: less than 5% per year.

The value of PPPs contribution, however, should not be underestimated because, putting aside the possibility of significant increases in public funding, they will likely be a primary model for building new highway capacity in heavily congested urban areas in the decades ahead. It is estimated that since 1989, the private sector has been involved in financing 56 US highway projects, roughly worth \$46 billion. Reinhardt (2011) explored the most important objectives of state Department of Transport (DOT) in using PF for highway projects. He finds that the most prominent objectives are:

- developing projects that otherwise would be delayed;
- enabling the agency to expedite the award of the contract to avoid future cost escalation;
- enabling the agency to start project procurement despite funding shortfalls for the project;
- incentivizing project teams to accelerate the completion of the projects;
- enhancing agency’s ability to overcome cash flow constraints.

State DOTs pursue these objectives to develop the backlog of their delayed projects and use deferred payment mechanisms in anticipation of future funding. On the contrary, objectives such as obtaining financing services beyond in-house capabilities, transferring financing and interest rate risks to the private sector, and encouraging competition and innovation are ranked relatively low in the list of major objectives. The relative ranking of objectives, provided by the survey respondents in the study by Reinhardt (2011), shows that state DOTs typically think of PF more as an instrument to bridge their funding gaps and financing shortfalls and less as an innovative solution to gain life-cycle cost efficiencies, encourage competition, and transfer critical project risks to the private sector.

Australia, as many other countries, need to invest significantly in new infrastructure to meet the growing demand of an increasing population. PPPs are a suitable vehicle for some economic infrastructures and can bring design and construction innovation, incentivize management and operational efficiency, early project delivery and improved asset utilization. Regan et al. (2017) reviewed six PPP projects: the Eastlink Motorway and Peninsula Link Freeway in Melbourne, the Airport Link and Clem 7 Toll Roads in Brisbane, and the Lane Cove Tunnel and NorthConnex Toll Roads in Sydney. They found that the Clem 7, Eastlink, Peninsula Link and Lane Cove projects were delivered ahead of schedule. In the case of Clem 7, this is remarkable given the technical challenges of the complex tunneling task. Airport Link also required extensive tunneling, but ran into technical problems causing late delivery and over-budget. Forecasting errors were the main reasons why three of the toll roads projects were placed in administration and another sold at a very significant discount to cost price. The commercial failure of four of the six projects suggests that in the absence of a more collaborative approach to risk sharing, financiers are unlikely to support future toll road projects in Australia. The task for government is to strike a balance between risk allocation and value for money outcomes on a case-by-case basis to sustain the PPP model. Nonetheless, Regan et al. (2017) concluded that PPP proved that large and complex projects can be delivered on time, within budget and produce better standards of services than traditional alternative procurement methods.

During the last few decades, the European Union has been promoting the use of PPPs in order to accelerate the development of the TEN-T network for ensuring economic, social and territorial cohesion and increasing accessibility within the EU (Garrido et al., 2017). To this aim, several mechanisms have been placed at the disposal of the Member States including:

- grants from European Regional Development Fund (ERDF) and Cohesion Fund (CF);
- grants from the European Investment Bank (EIB);

- and a series of innovative instruments such as:
 - the Loan Guarantee Instrument for Trans-European Transport Network Projects (LGT), designed to cover traffic revenue shortfalls during the initial operating period (ramp-up);
 - the EU Project Bonds Initiative, aimed at enhancing the credit quality of project bonds issued by private companies;
 - the Marguerite Fund (MF), a pan-European infrastructure equity fund established to act as a catalyst in the development of infrastructures in the transport and energy sectors.

Garrido et al. (2017) analyzed the case study of Spain and concluded that despite the EU effort to encourage the use of EU funds to support PPP projects, the application of the ERDF, the Cohesion fund and the TEN-T budget line has been very limited. Regarding the innovative financial instruments, their implementation at the time of the writing of this chapter had been quite modest in Europe in general, but particularly in Spain. Instead, the EIB's lending activity to PPPs in Spain is currently the largest EU support source even though the share of EIB loans given to PPP projects compared to other loans has not increased over the last few years.

Villalba-Romero et al. (2015) analyzed quantitatively and qualitatively four PPP case studies concerning road construction: the M-6 in the UK, the R-2 in Spain, the A-23 in Portugal and the Attica in Greece. The sustainability performance is compared against the "conventional" project management. Sustainability is measured by three pillars: economic, social and environmental; while the project performance is measured in terms of quality, cost, and time. They conclude that two cases, that is, A23 Portugal and Attica Greece, can be considered successful, while M-6 UK is more a success than a failure and R-2 Spain can be considered neither a success nor a failure.

PF for Innovative Transport Projects

Beside traditional transport infrastructure projects, government are now struggling to finance the next generation of sustainable transport infrastructures addressing problems such as climate change, air pollution, automobile dependence, and diminishing supplies of hydrocarbons. Initiatives aimed at fostering public transit, carpooling, car sharing, cycling, and walking need adequate dedicated physical infrastructures such as large scale urban rapid transit lines, interurban railroads, dedicated carpooling and car sharing lines, side roads for cyclists and pedestrians, parking areas, and fast charging stations for electric shared vehicles. Technological innovation such as Intelligent Transport Systems (ITS), Cooperative ITS deployment, and Mobility As A Service systems, might represent cost-effective, high added value solutions in order to spread the use of vehicle sharing and of public integrated services (Carvalho et al., 2018). In the coming future automated vehicles used both for public and private transport will need special connected and automated transport infrastructures requiring large investments that public sector cannot possibly face alone. PF could play a relevant role allowing the development and spread of these disruptive innovations (Voegel et al., 2017). The empirical evidence, however, suggests that it might be problematic using PPPs to finance sustainable surface initiatives because of the need to guarantee ongoing capital and operating subsidies from governments to make these initiatives financially viable (Siemiatycki, 2012).

Conclusion

Many countries find it difficult to carry out successfully transport projects. Developing countries might not have public funds available, while developed countries experience public budget restrictions that limit the country's infrastructure development. PPP appears to be an interesting mechanism for empowering countries, both developing and developed, and bring together public and private sectors to enhance transport infrastructures. PPP is not, however, a panacea. In order for PPP to deliver satisfactory results, some necessary preconditions should be met. They include a sound project master and implementation plan, a thorough and realistic cost/benefit assessment, an appropriate risk allocation and risk sharing, a balanced adjustment between the public and the private interests, a transparent and predictable legal framework, and a stable political and economic environment. PPP entails, however, also risks, widely discussed in the literature from a theoretical and practical perspective. Common mistakes leading to unsatisfactory results are overestimation of the demand, misallocation of risk between public and the private partners, and lack of a thorough assessment among alternative projects. Pitfalls result also from an excessive number of agencies dissolving responsibility and introducing inefficiencies and bureaucracy in the PPP processes, frequent changes in the regulatory framework, and lack of information on the gap between the current and the expected costs. When not properly carried out PPP might lead to biased decisions, usually favoring new "gold plated" transport projects instead of improving the existing ones, and an insufficient risk transfer to the private partners, with the public bearing most of the financial burden.

Definition of ITS

ITS stands for Intelligent Transport System(s). Intelligent comes from the Latin *inter-lego*, which means “I link together” or “I link with or through”; another meaning of *inter-lego* is “I read through”, which signifies being able to read between the lines, in other words being intelligent.

A deep comprehension of “intelligent” implies a wide and long-lasting path for ITS, here intended as “inter-connected” transport systems, which are able to include both humans—that is, travelers, drivers or supervisors of a control room, who contribute with their personal intelligence—and goods. This interconnection also allows motionless communication to be achieved, even during traveling (i.e., remote working, remote-courses, tele-conferences, tele-seminars, and tele-diagnostics), as the person involved is devoted to communication and not necessarily in driving, when needed.

This interconnection, and the presence of humans within the connected sub-systems, should have at least one purpose: to improve the safety, security, quality or efficiency of transport systems for passengers and freight, by optimizing the use of natural resources—including energy sources for the traction and propulsion of vehicles—and respecting the environment.

To achieve such aims, certain procedures, systems (including algorithms) and devices (such as sensors) are required to allow the collection, communication, analysis and distribution of information and data to and from moving subjects, the transport infrastructure and information technology applications.

In the 2030–40s, some ITS devices could have simply been identified as “Transport systems” (TS), without the use of an adjective (intelligent) that nowadays is not taken for granted. In fact, the 2020s can have the goal of “ferrying” the present transportation towards ITS, in order to possibly one day consider ITS as being just ordinary TS (Fig. 1).

Since ITS includes information technologies and—in certain cases—the mobility of people, some of the related topics may also be defined as “Infomobility”; such a concept, which stands for “informed-mobility”, can involve road transport, or any other mode of transport, as well as their mutual interactions, but it remains a part of ITS.

It should be noted that transport systems operating on fixed guideways—such as railways, undergrounds, ropeways and automated people movers—are interconnected and monitored by humans on a regular basis, right from their conception, through control rooms (Fig. 2). Road transport was not conceived in the same way: interconnecting its components is a goal that needs to be achieved through transport planning and a policy.

Finally, many synthetic definitions of ITS have been proposed. A complete one, although not the only one, has been provided by an association of universities that deal with ITS: “Intelligent Transport Systems integrate telecommunications, electronics and information technologies with transport engineering in order to plan, design, operate, maintain and manage transport systems. This integration aims to improve safety, security, quality and efficiency of transport systems for passengers and freight, optimizing

Figure 1 The transition of present transport systems toward renewed ones, passing through ITS, like the wheel in the past centuries

Figure 2 Control rooms for ITS: policy, planning, and operation.

the use of natural resources and respecting the environment. To achieve such aims, ITS require procedures, systems and devices to allow the collection, communication, analysis and distribution of information and data among moving subjects, the transport infrastructure and information technology applications". [ITS EDUNET, 2009].

Reasons for ITS in Transport Planning

A diffused, motorized, personal mobility—a long-term aim that might have inspired transport planning and policies at the beginning of the 20th century, when people and goods were mainly moved by horses and the first tramways—has generated also negative consequences over that century. These include environmental effects, unnecessary queues when traveling, traffic congestion and accidents, which are nowadays among the main causes of non-natural deaths for the under forties in many countries throughout the world. However, this pure motorized mobility is not necessarily informed, interconnected or intelligent.

Therefore, while one of the main goals of the long-term transport policy in the 20th century may have been diffused private motorization, the economic system of the 21st century has been marked by great changes, related to information technology applications, and is more environmentally oriented. These current trends, with reference to transport planning, are aimed at

improving the quality, safety and security as well as the energy efficiency of transport systems, many of which frequently already existed and were already in operation.

ITS is expected to facilitate this migration process towards systems with less queuing and optimised routes, through a better use of both road networks and energy, to prevent accidents, as well as the propagation of collisions, by informing the drivers, by fostering remote access to reservations (e.g., for parking areas equipped with plug-in electrified spots or for rail wagons devoted to road-rail transport of intermodal units) and payments (e.g., free-flow toll systems or free-flow access to parking garages), and by preventing injuries to people and damage to both the vehicles and the environment, in the broader sense. In this context, vehicles from necessity are becoming interconnected, in the pursuit of ITS.

ITS Applications

The main applications of ITS in *road transport* may be classified as follows (Dalla Chiara et al., 2017; Dalla Chiara et al., 2013).

1. **Monitoring traffic and road conditions**, such as vehicle flows, the related interruptions, the environmental situation and other information related to the road system, in order to:
 - a. obtain up-to-date information, including the occurrence of accidents or unexpected events, that can be transmitted to road and multimodal users, both in real-time along the infrastructure and possibly even before they initiate their journeys;
 - b. intervene in road system operations (opening/closing tollbooths according to the traffic, central traffic-light control systems, transit limitations, etc.);
 - c. plan possible interventions along the infrastructure, both under normal conditions and in the case of relevant events (a sports event, flooding, relevant damage of a road, etc.) in order to guarantee a given capacity, level of service and resiliency of a network or part of such a network;
 - d. schedule infrastructure maintenance works, by analysing the daily traffic volumes and trends, together with the environmental conditions.

Traffic data collection and automatic classification systems have the aim of detecting various traffic flow parameters, and this may involve just a simple counting, or establishing the position, spacing, headway, local and spatial speeds of vehicles, the traffic density or even the traffic volume. Different types of sensors or detectors are used to observe traffic parameters, and the use of one or more probe vehicles, equipped with sensors, moving within a traffic flow (a technique known as floating car data) is also possible (§ Data Collection through Automated Passenger Counting Systems and Traffic Sensors with the Related Networks and Fig. 3).

2. **Control and management of traffic-light systems**: traffic can be regulated through the use of stand-alone traffic lights, regulated at a local level, and by traffic control systems that are equipped with control rooms, at a wide area level, frequently on an urban scale.

The definition of a traffic-light control plan is normally determined on the basis of the observation of traffic flows (Fig. 4). These are estimated under the prevailing traffic conditions considering some typical daily trends, but they may also be influenced, in real time—through the abovementioned sensors—by a change in traffic patterns during the day or by the occurrence of emergency conditions that can affect a traffic flow, or even as a result of the introduction of priority policies (e.g., for public transport or emergency vehicles).

Figure 3 Monitoring traffic and road conditions for transport planning and traffic operation purposes.

Figure 4 Traffic monitoring: typical daily trends and an actual traffic condition according to data collected by sensors.

Figure 5 Monitored parking areas for either plug-in hybrid or fully electric private and/or shared automobiles.

3. **Control and management of parking**, which is sometimes given the term “park pricing”, is related to the devices and systems adopted to monitor the occupancy and parking duration of vehicles in a given site, and to calculate the respective fees. The devices used to control on-street parking are generally sensors or trans-receivers that are located outside a vehicle (in a parking control system), inside a vehicle (either installed inside a car or on a mobile device) or application accessible through the web (on the cloud). The integration of a number of devices through telecommunication systems, with user information systems and software for data processing, is recognized as a (dynamic) parking guide system. The availability and booking of electric charging for plug-in vehicles should also be considered for recent cases of electro-mobility (Fig. 5).
4. **Control and management of the passage of vehicles (transits)**, through physical or virtual barriers, with or without vehicles stopping. In this case, the entry of a vehicle into an area that is only accessible through one or more protected entrances is allowed through the use of mechanical-electronic devices or by paying a toll. Thus, the control and management of transit points with vehicle stops requires the use of devices to actuate the barriers that prevent access by vehicles not equipped with the instruments necessary to open such barriers and to collect a toll and/or issue a payment ticket. In the case of transit points without vehicles having to stop, the equipment includes devices that recognize the passage of a vehicle, or a person, so that information can be exchanged between the vehicle and the toll collection, or authorizing structure, and then verified. This approach has been applied to transport systems operating on fixed guideways, such as trains and undergrounds, for many decades. As far as roads are concerned, when dealing with the control and management of transit, reference can also be made to *road-pricing*, which can be technologically achieved through the simultaneous use of accurate automatic location systems (§ ITS: the Main Components) and telecommunications. The control and management of transit points for freight transport through ITS is useful for intermodal terminals or port gates, as they can simplify and speed up operations as well as avoid possible human errors. In this case, systems that adopt Optical Character Recognition (OCR) or Radiofrequency transmission Identification (RFid) can be installed and, in some continents, they are also compulsory to facilitate intermodal (road-rail, road-maritime) operations.

Figure 6 Transmitting information on-board through broadcasting, infrastructure-to-vehicle or vehicle-to vehicle information.

5. **Enforcement systems**, which can be introduced to pursue the application of motor vehicle or traffic codes along a road network, often for safety reasons. This objective can be achieved by introducing ICT devices and systems to ensure infrastructures are used correctly, with the application of fines when necessary. Typical examples of these systems are those based on image recognition and sensors or devices to detect the passage of a vehicle (e.g., red light cameras at traffic lights or in limited urban areas) as well as speed violations.
6. **Traffic and traveler information systems**, which use data that are made available by the managers of the road infrastructure or traffic data providers. Information can be transmitted either by means of on-board systems or through ground systems. On-board information may imply either broadcasted information to all the vehicles moving in a given area (a region or an entire nation) or personalized information requested by an individual user. In the last century and at the beginning of the 21st century, road user information was primarily based on RF analogue transmission. However, more up-to-date systems exist, with the related services on the radio broadcast market, such as RDS-TMC (Radio Data System - Traffic Message Channel), DAB (Digital Audio Broadcasting) and DVB (Digital Video Broadcasting), all of which allow on-board information to be transmitted. Other alternative systems that can be used are short-range RF or infrared communication systems (DSRC, Dedicated Short-Range Communication) or even cellular networks (Fig. 6).
Data exchanged through ground devices can be transmitted to travelers through variable message signs or panels installed along a road/motorway network (Fig. 3) or along public transport routes or near interchange areas, and computer kiosks, as well as by means of infrastructure-to-vehicle communication (§ ITS: the Main Components).
7. **Driving assistance, on-board route guidance and navigation**, which are related to driving assistance systems pertaining to the instantaneous operation of the vehicle, information on the road network and any traffic limitations or immediate requests for assistance, the police and ambulance interventions.
Therefore, these pertain to a number of on-board sensors, which can help the drivers attain safer driving, to launch an emergency call, or use a navigation process that suggests how they should drive to a given destination at the minimum cost or in the shortest time.
8. **Control and management of passenger transport services**, a process which involves the monitoring of fleets of various categories of public transport vehicles, such as trams, buses, taxis and shared services (usually cars and bicycles, and nowadays also scooters and electric scooters). The operating conditions, functional conditions, actual occupancy (passengers on board; § Automated Passenger Counting) and position of the vehicles are in particular monitored.
9. **Integration of the above-mentioned applications**, which results in a wide-spectrum control of mobility and freight, that is, control that includes interoperability and compatibility with other systems at an urban, regional, national, and international level.

ITS: the Main Components

Considering the high number of vehicles on roads, which has been rising globally during the last century, many transport systems frequently struggle with congestion, in both space and time. Transportation by itself is no longer enough since society currently not only requires people to be moved and freight to be forwarded or handled, it also requires updated information. ITS can associate information to physical transport devices and can be decomposed into the following basic technological supports or classes of components [1, 2].

Telecommunication Systems

Telecommunication includes a vast array of technological solutions, networks and devices that allow information to be transmitted over various distances. Telecommunications lay the foundations for ITS, as all their applications involve the transfer of data and information, in real time when possible, between moving subjects and information technology applications (sensors, centralized control rooms).

These systems can include different mobile communication technologies:

- fixed networks, for public or private access;
- mobile networks for public or private access:
 - point-to-point and point-to-multipoint communication, with public-access mobile radio networks, such as 4G-5G, or with private mobile networks, such as PMR (private mobile radio), or be based on specific network services dedicated to road transport operators or applications, such as DSRC and co-operative driving, including vehicle-to-vehicle or infrastructure-to-vehicle communication;
 - broadcasting systems (such as DAB and DVB, § ITS Applications), to distribute information to moving vehicles and to travellers' mobile devices.

Automatic Vehicle Location Systems (AVLS)

AVLS is an ensemble of methods and technologies aimed at automatically determining the geographic location of a vehicle or of a personal device (i.e., a mobile terminal) and at making the information available or transmitting it to a requester. The main methods include:

1. the utilization of inertial instruments (such as accelerometers and gyroscopes) and odometers, which have been used on board for some decades;
2. automatic location systems based on tri-lateration or multi-lateration, such as GPS (USA), GLONASS (Russia) and GALILEO (European Union);
3. mobile cellular networks;
4. systems based on automatic identification devices distributed along a given pathway, which are being used more and more frequently, but not necessarily exclusively, for transport systems operating on a fixed guideway (trains, trams, undergrounds and the like).

These methods can be combined together to increase the continuity or the accuracy of each of them.

Automatic Identification Systems (AIS)

Automatic Identification Systems (AIS) are principally used to locate and identify certain attributes of objects passing through an open or closed system. The most important available AIS technologies are:

- radio frequency identification (RFid);
- bar-codes and bi-dimensional codes;
- magnetic-strip cards;
- smart cards;
- identification by means of video technology;
- biometric systems.

RFid and smart cards include, for example, ticketing systems for public transport. A possible application of these AIS is that of Near Field Communication (NFC), a bidirectional wireless connectivity (RF) that operates over a short range, which represents an evolution from contactless identification, or RFid, and other connectivity technologies. NFC allows bidirectional communication when two instruments are close, that is, within a few centimetres; a peer-to-peer connection between them is activated and both can send information.

Data Collection for Traffic Flows or Passengers Through Sensors and Their Related Networks

Traffic data concerning either vehicles or passengers can be measured using sensors of various types, each of which differs according to its application, performances and costs, that is, its purchase, installation and maintenance costs. These sensors and their related networks are analyzed later on (§ Traffic Data Collection).

Electronic Data Interchange (EDI)

EDI represents a simple concept: the use of direct links between computers and information technology applications, even between systems at different sites, to transmit data in a predefined way (e.g., EDIFACT, XML, . . .) that would otherwise usually be sent in printed form or in an informal, not easily manageable way.

Cartographic Databases and Geographic Information Systems (GIS)

A GIS allows data represented on a geographical base to be viewed, understood and interpreted in various ways that reveal relationships, patterns and trends in the form of maps, reports and charts.

When considering any ITS application, it is easy to verify whether it is constituted at least by a communication support (§ Telecommunication Systems) and possibly by one or more of the other components (§ Automatic Vehicle Location Systems (AVLS); Cartographic Databases and Geographic Information Systems (GIS)); therefore, the aforementioned groups of technologies, together with the already mentioned sensors, instruments and data collection systems, may constitute the basic bricks of any ITS: data collection systems are dealt with in detail in the following section.

Their applications can be expected, in various integrated forms, for the third decade of this century in order to attain:

- *smart roads*, which are expected to automatically recognize what is happening above them and then rapidly inform the travelers, through the use of staffed control rooms;
- *assisted driving* (§ Driver Assistance and Road Safety Technologies), as a probable intermediate passage towards automated vehicles.

Data Collection Through Automated Passenger Counting Systems and Traffic Sensors With the Related Networks

As has emerged from the previous section, data collection plays an important role in transport policies, transport planning, traffic engineering and in managing the capacity, in the field of traveler information, road management systems, parking management, as well as emergency management, where reliable traffic data are needed (Dalla Chiara et al., 2017; Dalla Chiara et al., 2013).

Automated Passenger Counting

Passenger counting has always been a key activity in the planning and development of public transport: many agencies measure part of their results on the number of people who use their service. The importance of an accurate analysis of passenger flows has been known for decades; the collection of data has traditionally been the duty of personnel appointed to report the load status on board. Manual collection is still the most widely used method in the world. However, this is unable to provide a continuous, fast and accurate control; hence the need for automated tools, which can be supported—if required—by traditional systems.

The options available nowadays include monitoring systems based on payment methods, such as fare collection machines and the use of smart cards. Technologies identified as APC (Automatic/ed Passenger Counting) are appropriate for this purpose and of great interest for the analysis of data. A great variety of passenger counting technologies are available on the market; no single solution can be considered as the best or the most economically convenient a priori. The modalities adopted to count people on tramways, buses and trains can therefore be summarized in the two following categories, namely:

1. Counting irrespective of a ticket:
 - a. monitoring of single individuals, usually by technologies on board the vehicle;
 - b. monitoring of the overall load on the means of transport, with technologies applied to the pneumatic suspensions or to the ground;
2. Counting related to the ticket, including the possibility of requiring checking-in and checking-out when using a public transport service.

In the former case, the counting can be based on either the detection (or attempted detection) of the single individuals or indirectly, usually by ascertaining the weight of the vehicle under the passenger compartment or on the infrastructure. Whatever method is selected, the objective is that of obtaining a reliable, accurate counting, or—at least—whose margin of error is contained within a few percentage units, compared to the actual number of people present on the public transport vehicle.

Counting irrespective of a ticket is carried out by means of appropriate sensors, which may detect the passage of people through gates, usually the bus, tramway and train doors. A possible solution is based upon the use of infrared sensors, which act as active switches; in the case of passive switches, pyroelectric sensors can be used. In some applications, only infrared ray switches are used, while double sensors (e.g., active and pyroelectric IR) are used to enhance the reliability of the counting.

Sensors applied to the pneumatic suspensions of a vehicle to reveal the weight, and consequently the number of passengers on the basis of an average weight, and video cameras with image recognition can also be successfully used for this purpose.

The counting of passengers by automatic means provides a huge amount of data, in terms of continuous flows of information, but also of diversified information which can be easily transmitted and correlated in order to acquire an overall view of the phenomenon. This context includes the capability of coupling AVLS with APCs in order to merge the data relevant to the load status, linked to the infeed and outfeed times or timetables at the stops, with the position data, for a continuous monitoring of a line.

Traffic Data Collection

Two primary detector technology categories can be distinguished (Klein, 2001):

1. with intrusive sensors, which need to be installed above or under the road surface;
2. with nonintrusive sensors, which implicitly offer the advantages of the traffic flow not being disrupted during their installation and their maintenance.

In addition to intrusive and nonintrusive detector technologies, other advanced methods, such as data from mobile phones, probe vehicles and remote sensing (by satellites or drones, when applicable and whenever conditions do not compromise their usage), could offer the possibility of detecting travel times and traffic volumes.

Moving Sensors or Sensors in Motion

Traffic and road conditions can be monitored by equipping one or more probe vehicles within a traffic flow, a technique that is known as floating car data. This permits the acquisition and real time analysis of space–time variables of motion, and thus of traffic, for comparisons—if necessary—with data from devices external to the vehicle (§ Static or Portable Sensors, together with sensors to measure environmental parameters and polluting emissions, etc.). Information on positions and speeds, acquired instantaneously by the floating car, can be determined by processing the signals coming from an automatic, satellite-based, location system and, in certain cases, by inertial instruments mounted on board such a vehicle.

Static or Portable Sensors

At present, the main instruments available for the automated collection of traffic data installed along a road network can be classified as follows (Klein, 2001).

- **Pneumatic instruments**, such as pneumatic road tubes. This was the first intrusive-type of traffic detector to be used, and it is still sometimes used for the short-term counting of traffic flows because of its simplicity and low cost. Pneumatic road tubes can also detect the volume and speed of vehicles, and classify them according to an axle count and spacing.
- **Inductive Loop Detectors (ILD)**, which are possibly the most commonly used sensors in traffic management applications; they operate by sensing disturbances to the electromagnetic field over a wire coil inserted underneath or inside a road pavement. A lead-in cable runs from a roadside pull box to the controller cabinet. Recent versions of ILD use higher frequencies to identify specific metal portions on the vehicle, which can then be used to classify the vehicles. Inductive loops are sensors that are commonly used for vehicle counting because of their high performance and low cost, compared to other technologies; they can be used to detect the volume, presence, occupancy, speed and class of vehicles using a single or a dual (speed-trap) loop configuration.
- **Magnetic sensors**, which are also known as magnetometers. They measure the disruption in the earth's magnetic field caused by the presence of a metal vehicle. Magnetic sensors are often used in place of loops on bridge decks, where ILDs cannot be installed, and in heavily reinforced road surfaces. Magnetic detectors can detect the volume, speed, presence and occupancy of vehicles, and they are not affected by inclement weather.
- **Piezoelectric instruments** are made up of a piezo-electric material that may convert a mechanical deformation into an electric signal. When a vehicle's axle passes over a piezoelectric device, it generates a voltage by causing electrical charges of opposite polarity to appear at the parallel faces of the piezoelectric crystalline material. The measured voltage is proportional to the force or weight of the vehicle. The adoption of this kind of detection system (generally called Weigh In Motion, WIM; § Specific Weigh-In-Motion Sensors) enables information to be acquired on the typology of the vehicle (load axles, overall weight) which can be added to more conventional information (traffic flows, occupation rates, headways or distance between vehicles, as well as to information on the speed and length of the vehicles themselves).
- **Microwave Radar Sensors**, which represent one the most important non-intrusive detector technologies. Two types of microwave detectors are available: Doppler Microwave Detectors and Frequency modulated Continuous Wave (FMCW) Detectors. The Doppler principle is used to calculate the speed of a vehicle from a continuous wave (CW) microwave radar that transmits electromagnetic energy at a constant frequency. Since only moving vehicles are detected by a CW Doppler radar, the presence of a vehicle cannot be measured by this waveform, and this kind of radar can only detect the volume, occupancy, classification and speed of vehicles. FMCW detectors, which are sometimes referred to as true-presence microwave detectors, transmit continuous frequency-modulated waves from the detection zone, and can detect both the speed and presence of vehicles.
- **Infrared sensors**, which can operate in either active or passive mode. In the former case, the detection zones are illuminated by means of infrared energy transmitted from laser diodes operating in the near infrared spectrum. A portion of the transmitted energy is reflected by any vehicle traveling through the zone. The reflected energy is focused, by means of an optical system, onto an infrared-sensitive element that is mounted at the focal plane of the optics. The infrared sensitive element converts the reflected energy into electrical signals that can be analyzed in real time. The presence of a moving or stationary vehicle is determined by measuring the round-trip propagation time of the transmitted infrared pulse. Active infrared detectors are affected by snow and rain, because short wavelengths cannot penetrate them. Vehicle speed is measured using two fixed beams, one pointed slightly ahead of the other. Passive sensors do not transmit energy: they instead detect the energy that is emitted or reflected from vehicles, road surfaces and other objects in the field of vision and from the atmosphere. Multi-zone passive infrared sensors can measure the speed and length of vehicles, as well as estimate the more conventional vehicle count and lane occupancy.
- **Ultrasound devices**, which are also known as ultrasonic sensors, generally transmit sound energy pressure waves at frequencies that are above the human audible range. Most ultrasonic sensors operate with pulse waveforms and they can provide vehicle count, presence and occupancy information. Pulse waveforms are used to measure distances from the road surface and vehicle surface, by detecting the portion of the transmitted energy that is reflected toward the sensor. The received ultrasonic energy is converted into electrical energy, which is analyzed by means of signal processing electronics. The speed of a vehicle can be measured by transmitting the pulse energy at two calibrated, closely-spaced incident angles. Constant-frequency ultrasonic sensors that measure speeds using the Doppler principle are more expensive than pulse models.

- **Passive acoustic systems**, which are able to measure the flow rate, occupancy and speed of vehicles by detecting acoustic energy in the form of audible sounds. The sounds are produced from a variety of sources from each vehicle, and from the interaction of the vehicle's tyres with the road. When a vehicle passes through the detection zone, a signal-processing algorithm recognizes an increase in sound energy and generates a vehicle presence signal. When the vehicle leaves the detection zone, the sound energy level drops below the detection threshold, and the vehicle presence signal is terminated.
- **Video technology**, which consists of Video Image Processors (VIP), detects vehicles and, in case of need, their number plates, by analyzing video images in order to determine the changes between successive frames and applying Optical Character Recognition (OCR) techniques; some versions also include the tracking of a vehicle in motion, sometimes finalized at road pricing. A VIP system usually consists of one or more cameras, a microprocessor-based computer to digitize and process the video imagery, a software to interpret the images or characters and convert them into traffic flow data. The image processing algorithms in the computer analyze variations in the color or gray levels in the groups of pixels contained within the video image frames. Heavy rain, strong wind and snow can reduce visibility, and the reflection of images from wet road surfaces also affects the performance of VIP systems.
- **RFid and radio wave identifiers**, including Bluetooth e WIFI scanners, are used to count traffic and to identify the origins-destinations of monitored devices, typically at a local scale. Their use is associated with—for example—the identification of road vehicles entering and leaving terminals, in order to quantify both the traffic and time requested for the transit time through the terminal.

Specific Weigh-In-Motion Sensors

Weigh-In-Motion (WIM) is a technological solution that allows the load exerted on a road by a moving vehicle to be measured in order to estimate the static load of the vehicle.

WIM can provide the real-time data of traffic flows, the total weights of vehicles, the weight of each axle, the type of axle and the classification of the vehicles themselves, and therefore results in numerous useful applications related to transport planning and policies, mainly pertaining to road pricing when pricing is also associated with the weight classes of the vehicles.

Their main applications are listed hereafter.

- **Traffic Monitoring and Management**: the management of traffic in real time, the classification of vehicles on the basis of their weights, and the protection of bridges from being overloaded.
- **Road surface design, monitoring and research**: estimation of the equivalent single axle load, the classification of roads (depending on the percentage of heavy-duty vehicles) and the study of the relationships between the axle load and damage to a road.
- **Toll Collection**: whereby an appropriate road user charge is imposed on vehicles on the basis of their axle loads.
- **Environmental studies**: to point out the relationships between emissions and the total weight of a vehicle.

A WIM station is usually composed of:

- a. proximity sensors, which are able to measure flows, headways or distances between vehicles, as well as the speed and lengths of different vehicles (§ Static or Portable Sensors). They indicate the presence or arrival of a vehicle, and they trigger the weight sensors to make them active in order to record at an appropriate moment;
- b. devices and detectors of various kinds, which are able to provide, through dedicated software, the weight of each axis, and the distances between the axles of each vehicle in order to obtain the different transited shapes (of the vehicles);
- c. a supply unit with a central unit, which is able to elaborate and manage information obtained from the sensors and from detectors, such as inductive loops, and to record them;
- d. a connection system of the different stations, by means of a modem, GSM or GPRS, or other communication supports;
- e. dedicated software programs for the analysis and statistical elaboration of the collected data, as well as software programs that are able to guarantee the quality of the measurements.

Wireless Sensor Networks

A Wireless Sensor Network (WSN) is a network made up of small sensor nodes (SNs) that communicate with each other using wireless communication. It combines distributed sensing, computation and wireless communication technologies. Conditions, such as temperature, noise, vibration, pressure, motion and pollutants, can be monitored at a large scale using a spatially distributed WSN. Because of its variety of functions and flexibility of deployment, numerous applications, including road traffic detection and more long-term transport policies, may be developed using WSNs. A WSN can constitute the base of a "smart road" (§ ITS: the Main Components).

Driver Assistance and Road Safety Technologies

As far as automobiles and, in general, road vehicles are concerned, their evolution during the second and third decades of the 21st century was closely related to ITS and in particular to their connectivity (vehicle-to-vehicle and vehicle-infrastructure communications) and assisted driving, which one day may be autonomous. Mere passive safety features (such as safety belts, headrests and air

bags), although still vital, have been associated with other technologies, and other safety factors have also been considered important since the beginning of this century, namely:

- **active safety**, which ensures that the driver has the greatest possible control of a vehicle and increases the likelihood of avoiding an accident;
- a **preventive system**, which prevents the occurrence of those conditions that could generate an accident. Such a system is relevant to foster concentration, comfort and any other aspect that can facilitate driving and inform a driver about the road conditions and potential hazards.

As far as active systems are concerned, this definition also includes road signs – whose preventive function is the very reason for their existence – with future communication systems or image detection on-board software that may be able to show the aforementioned road signs on the instrument panel of a vehicle. Moreover, the roads themselves, when well designed, developed and maintained, might also represent an element of active safety. The main safety devices or systems that have been quite common on newly designed cars since the second decade of this century include ABS (Anti Brake-Locking System), ESC (Electronic Stability Control), VDC (Vehicle Dynamic Control), BDC (Brake Dynamic Control), TCS (Traction Control System) and EBD (Electronic Brake Distribution). However, other active safety systems also exist, namely:

- anticollision systems;
- alert systems for the communication of hazards or obstacles;
- systems to detect a driver's behavior and conditions, or for the automatic correction of driving errors.

Modern road vehicles are generally equipped with such systems, that are usually recognized as Advanced Driver Assistance Systems (ADAS), as: Intelligent Speed Adaptation (ISA), Seat belt reminders, Alcohol Interlock Systems (AIS), In-vehicle event data recorders (EDR), Autonomous emergency braking systems, Anti-lock braking for motorcycles and Lane Keeping Warning Devices (LDW).

It is necessary to bear in mind that a great number of road accidents with casualties occur under poor visibility conditions, that is, at night or in the case of fog. Different types of sensors are, or could be, used to obtain information about what is occurring around and ahead of a vehicle. The most frequently used or usable ones in the automotive industry are ultrasound sensors, infrared sensors, radars, lidars and artificial vision.

Each sensor operates over a different range of electro-magnetic spectrum frequencies and supplies partial information on the space around the vehicle. A combination of these sensors might provide better results than the use of a single one. The first applications of these systems were for the automatic control of speed. Using either a microwave or laser radar, a vehicle manages to perceive the presence of another, slower vehicle in the same lane and therefore slows down to adapt to the speed of the preceding vehicle. This function is called Adaptive Cruise Control (ACC).

As far as the lateral control of a vehicle is concerned, sensor systems, based on cameras, may help a driver to keep to the same lane and prevent him/her from going off the road. Research is also being conducted on automatic steering control systems (lane keeping). Other examples of drive support functions are night vision (based on infra-red cameras), blind spot detection (the driver can be informed about the presence of an overtaking vehicle in the blind spot area on the side of the vehicle), sign recognition and support during parking maneuvers (parking sensors and, in more recent vehicles, steering-control). All these technologies allow a vehicle to be more integrated with the environment where it is driven and to support the interconnection of the driver, the vehicle itself and the infrastructure, thereafter pursuing ITS as defined above.

Inter-Vehicle Communication (IVC) systems play a significant role in enhancing the performance of traveler information systems. Inter-Vehicle Communication can be defined as the communication and cooperative exchange of data between vehicles via wireless technologies, within a range that can vary from a few to a few hundred meters; vehicle-to-vehicle (V2V) is another frequently used term when referring to direct communication between vehicles, without any external support.

Vehicle-to-Infrastructure (V2I), Infrastructure-to-Vehicle and Road-to-Vehicle Communication are all forms of cooperative wireless interaction between an infrastructure and a vehicle system, which are used to improve the safety and performance of both the infrastructure and the vehicles; V2I could also imply mobile Internet access, to provide support for the mobility management of vehicle users. V2I communication requires an infrastructure, through which the participating mobile units (vehicles) can transmit their data to the control center.

The Technological Scenario: A Vision

The first sets of technologies and applications of ITS for transport planning and policy were based on data collection and system monitoring, pertaining to the mobility of people, to traffic and to the transport of goods, with the related logistics. Such systems resort to already existing optical, electric, magnetic, radar, laser, acoustic, piezoelectric, pneumatic, pyroelectric and beam-based devices, and they also include Wireless Sensor Networks (WSN). The WSN paradigm consists of a large ensemble of heterogeneous, battery or self-powered sensors, interconnected to one another by means of wireless technology. The use of such interconnected wireless devices generates a widely and densely deployed infrastructure of sensors, which collect information about the utilization of the road surface by vehicles, their number and respective weights, as well as the environment conditions.

The merging or fusion of such a huge amount of data allows their points of departure and final destination (O/D) within the network to be known, in order to ascertain the flows, and information about the use of the network, the road surface conditions, the

rapid identification of accidents, traffic congestions, the level of service (LOS) of a road and the like to be rapidly identified. Such data can be compared or integrated with other data obtained from probe vehicles, through the so-called floating car applications. All these aggregated data can be used to attain a significant improvement in safety through the optimization of the management and control of a road network and through the tailoring of the road-maintenance schedules, and can even be associated with a Geographical Information System (GIS).

The communication of these data to an infrastructure manager can be either automatic or simply assisted, and they become instrumental in providing support for local applications as well as for more extensive purposes, such as flow monitoring and control through dynamic route guidance. All the collected and processed data can become useful at both the planning and operational level: for fleet management, for both passengers (i.e., public transport services, taxis, shared vehicles, multimodal platforms that is, the usage of different transport means through a common card, as the concept of mobility as a service, identified with the acronym MaaS) and for freight transport, as well as for the related logistic activities, such as the monitoring of containers, swap bodies and semi-trailers in intermodal transport contexts. On-board navigators, for private or personal use, may also resort to the information made available by the mobile Internet access scenario, and thus accidents, queues, dense fog and interruptions on carriageways can be avoided in real time, or the route taken to reach a certain place or event of interest may be changed.

Biography

Bruno Dalla Chiara is full professor at the Politecnico di Torino in the field of Transport Systems (since 2019) and was previously associate professor in the same university and academic field. He holds a Master of Science in Mechanical Engineering, with specialization in transport systems, engineering and economics (1993), and a Ph.D. in Transport Engineering, with specialization in ITS (1997). He holds or has held the chairs, at the Politecnico di Torino, in "Rail transport systems, urban transit and rope installations", "Transport systems and external logistics", "Mobility" and "Transport planning". He is the author of several publications, mainly concerning the engineering and design of transport systems, ITS, rail and intermodal transport.

Introduction

The purpose of this chapter is to highlight how the continuous processes of socio-technical transition impact on the field of transport planning, and to reveal how at times, developments converge to make certain technological developments more “disruptive” to the status quo and to the ability to plan. The history of transport systems, at least over the last 300 years, is one that has been profoundly shaped by technological invention (Rodrigue et al., 2009) which is closely entwined with an ever-growing demand for transport as the developments increase human reach, both temporally and spatially and become more embedded in wider social practices (Rinkinen et al., 2020).

In transport, there is a lot of anticipation about the potential for new technologies and services to deliver solutions to some long-standing and rather intractable problems, such as congestion, air pollution, and carbon emissions. Concern in the health sector regarding the impacts of sedentarism arising from overdependence on cars also drive behavioral policy moves to increase active travel. It is increasingly important that cobenefits of change can be identified and promoted, and also that nontechnological solutions are deployed alongside.

Many of the current developments in transport involve the use of digital technologies in some form, and can be grouped under the descriptor “smart mobility.” However, this is a fuzzy concept, “perhaps more a label with currency than anything specific” (Marsden and Reardon, 2018, p. 2). Nevertheless, it is one which has achieved that currency precisely because there are a number of key shifts occurring, involving both electricity and digital communications technology (the “smart” part), which are already impacting on how we get around: electrification of vehicle fleets (which itself consists of several different technologies); growth in online retailing and working away from the workplace impacting on previous trip patterns; the convergence of mobile Internet, geospatial tools, and handheld portable devices underpinning the rise of the “app,” generating enormous amounts of new data and data traffic to and from consumers; the latter development is leading to a proliferation of new business models for shared and micro-mobility services such as station-based or free-floating bike hire, car sharing, ride-hailing, and parking management. Further away from widespread use are fully autonomous, or self-driving vehicles, though many existing vehicles increasingly have a number of automated features, such as hands-free parking, or lane control. The infrastructure itself is also increasingly instrumented, gathering and transmitting data that is used to monitor, manage, and enforce.

While traditionally these innovations are seen as meeting some kind of need or demand (to boost or unstick the economy for example), it is increasingly evident that technological innovation shapes that demand in ways that are usually unanticipated, even once the phenomenon is recognized (e.g., the concept of induced traffic demand). There has also been inertia in the deterministic forecasting systems that are in common use for transport planning and project appraisal, in which existing trends are extrapolated out into the future with little reference to either social or technological change. Before proceeding to explore the challenges (such as uncertainty) that these innovations or “disruptive technologies” pose to transport planning, the concept of transitions is explained.

Concept of Transitions

The concept of transition is one involving change, moving from one state to another state. As change is a continuous, uneven and inevitable process, this can pose some challenges for efforts to plan, steer, and control human activities. Furthermore, the nature of large-scale transition is often not clear until some way into the process—at what point during a process of change can we say that there has been a fundamental shift in the balance of power, the way things are done, in the state of an ecosystem or network or in terms of which technologies are dominant? Kemp and Loorbach (2003) suggest that transitions take one or two generations. Climate change is a particular example that illustrates how difficult it is to be certain about whether tipping points are close to being reached

or have already been passed, as any single incident of severe weather cannot with certainty be said to be “because of climate change,” but patterns of increasingly severe weather are certainly evident yet responses to the threat are highly variable (Eriksen et al., 2011). Transitions in ecological states are a driver of calls for human activities to change to be less damaging, to mitigate damage that is already occurring, or to adapt to changes that cannot be reversed. In this sense, transition is something that we seek as well as experience. As many of the changes that are seen as necessary are both societal and technological, including within the field of transport, the term socio-technical transition is a key concept, though there are related concepts, such as transformative change (e.g., O’Brien, 2016).

There are several strands of literature, utilizing a range of theories and conceptual frameworks to consider processes of transition and transformative change in the context of global challenges of climate change and sustainability, which collectively have influenced the emergence of the field of “transition studies” (Rauschmayer et al., 2015; but see also suggested further reading). What they tend to have in common is an emphasis on the connectedness of social and ecological processes, the pressing need for conscious and inclusive steering of change to avoid the worse consequences and the role of technology as just part of a more profound set of changes, not a solution in its own right. Some of the literature is theoretical in seeking explanations of what is (e.g., socio-technical transitions theory, and the associated multilevel perspective), whereas other contributions are more action oriented, such as transition management, which aims to operationalize transitions toward sustainability in governable ways, through a focus on the role of actors in processes (Jhagroe and Loorbach, 2015).

In terms of transport planning, the transition could be seen as *paradigmatic* (see Kuhn, 1962) with the new planning goals, tools, and processes linked to sustainable mobility being introduced in a rather piecemeal manner, whilst old planning goals, tools, and processes linked primarily to reducing congestion, still dominating the existing institutions and practices (Bertolini et al., 2008). The transition for transport planning remains therefore a complex challenge in many places around the world. A number of authors have provided insights into transitions thinking in transport planning, with some advocating a broader view to include case studies of nonwestern socio-technical transitions (see Hopkins et al., 2020). Some interesting examples are found in Ghosh and Schot (2019), Sengers and Raven (2014), and Sunio et al. (2020).

Concept of Disruptive Technologies

The concept of a technology being disruptive refers to the potential for introduced inventions to disturb how things have been done up until that point. Indeed, in relation to transitions, some degree of disruptiveness might be seen as the point, in that there is a perceived need to disturb the status quo. In the transport sector, this refers to the possibility that the new services and business models have a large impact on the practices of incumbents, often to the point of threatening their viability as going concerns. Indeed, the business models of the new actors are often explicitly posing a challenge to existing providers, as the promoters perceive an opportunity to profit from better meeting the needs of the customer or end-user in some way (Marsden and Reardon, 2018). Ride-hailing companies which match drivers to passengers are a commonly cited example of this, for the way they have used weak regulatory systems to aggressively compete against traditional taxi operators and licensed private hire companies, something which is explored in more detail below.

A new technology-enabled user-centric business model that integrates multiple transport modes is mobility as a service (MaaS). This is a platform-based concept that is at the forefront of the minds of decision-makers, though it is contested as to whether it is a truly new concept (Lyons et al. 2019). Whilst there are only a small number of extant examples of MaaS that are operating as more than just pilot schemes, there is an increasing amount of literature, gray and academic, exploring the potentials and implications of MaaS to provide integrated and efficient transport. Networks have formed to promote the concept (e.g., Europe’s MaaS Alliance or MaaS Scotland in the UK) and it is being encouraged by policy-makers. In Scotland, Transport Scotland have launched a Mobility as a Service Investment Fund to stimulate near-market pilot schemes and trials. In Finland, which is commonly held to be the origin of MaaS as a term, a legislative change was made in order to facilitate MaaS’ entry into the transport ecosystem, though this is not an approach that has yet been replicated elsewhere (Hensher et al., 2020). However, MaaS Alliance, which is a public–private partnership body, are clear that regulatory facilitation should happen, ultimately compelling transport service providers to digitize their practices and develop APIs to feed timetables, real time information and booking/payment facilities to end users via MaaS platforms. This makes the platform provider a new broker in the system, with the power to negotiate price with the service providers, and then develop bundles of services and payment options that are marketed to the consumer.

The disruptiveness of MaaS is the breaking of the direct relationship between transport service providers and their users. While this is perceived as reducing the cognitive effort of trip planning, there are likely to be some unanticipated negative impacts, such as for overall levels of demand for travel by different modes, as well as some socio-distributional effects with equity implications (Pangbourne et al., 2020). However, there are other individual developments, such as ride-hailing (Uber, Lyft), micro-mobility (bike and scooter sharing) and, to a certain extent the concept of shared autonomous vehicles, that have dominated much of the discussion about disruption in transport. The common denominator among this apparent diversity is the ubiquitous technologies, such as GPS and smartphones, that have facilitated their growth and development. Attard et al. (2016) provide a review of such technologies in the transport sector which have and will evidently continue to impact transport in the future.

The entry into the transport ecosystem of all of these innovations poses challenges for transport planning. First, the producers of these inventions are looking for markets and seeking to ensure that their products are accepted and facilitated. The alliances that form around certain developments, such as MaaS, are very active in pushing for acceptance, including advocating for legislative and

regulatory enablement. Second, it takes time for evidence to emerge as to the effects, good, or bad, of the technologies either as they are developed through industry and government supported trials and pilot schemes or once they are operating as start-ups funded wholly through the private sector. This hampers the ability to appraise and compare potential innovations and transport infrastructure projects. Third, the new forms of mobility create new affordances which impact on social practices in a mutually shaping relationship, which increases the challenge of steering for transport planning, as many of the shifts in practices are not directly within the sphere of transport. Finally, some technologies seem to have more fundamentally disruptive potential than others, and thus demand different levels of attention and generate differences of opinion about their worth from transport authorities and planners.

For example, [Stone et al. \(2018\)](#) examine the preparedness of Australian transport agencies in relation to planning for the deployment of autonomous vehicle (AV) technologies. On the whole, as the development of fully autonomous vehicles has been “five years” away for some time, despite public funding going into trials in many countries, it is very hard for transport planning to take the possibility of *profound* disruption into account in their usual planning horizons. Consequently, there is still a general tendency to take dichotomous positions based on utopian/dystopian visions and scenarios, with the position on car dependency often being a key determinant. [Stone et al. \(2018\)](#) suggest that some transport planners would argue for AV if they are designed to be integrated with existing public transport services, as well as with active travel (walking and cycling) because this would be the most efficient way of providing better accessibility for everyone while reducing overall traffic congestion and pollutants. However, if the business model used for AV is one of individual private use (owned or leased), then none of these benefits can be guaranteed, and congestion could worsen. [Stocker and Shaheen \(2017\)](#) reviewed work examining the likely impacts of different AV business models and found no clear picture, due to the small scale of existing trials, but identified a wide range of possible impacts. Given the almost total uncertainty over when the technology will be “street ready” and widely adopted, with the initial regulatory effort mostly focused on the safety and legal aspects of AV, there is little that transport planners can do to prepare strategically for the potential disruption, something that was revealed empirically by [Guerra \(2016\)](#).

Issues and Uncertainties Arising From Transitions and Disruptive Technologies

In the absence of empirical evidence of the effects of candidate innovations, we can look to past transitions for insight around the types of issues that can arise. [Geels \(2005\)](#) analyses the transition pathway in the shift to steam power on land and in international shipping, describing the disruption to the incumbent regime of horse and sail power. [Urry \(2004\)](#) analyses the transition to widespread car dependence and dominance through the conceptual lens of automobility. [Rinkinen et al. \(2020\)](#) describe many examples of interlocking technological and social developments that collectively shape and reshape the evolution of demand for energy and transport through their impact on social practices, including the timing of collective endeavors such as commuting or education and how that impacts on such diverse activities as transport, holidays, domestic tasks such as laundry, dishwashing, and cooking, and even when we watch television, with the concomitant impacts on the timing of peak energy or transport network usage.

The work of Geels et al. on the multilevel perspective of socio-technical transition highlights that there are many barriers to innovations moving from their niche (whether that is a laboratory or a demonstration project) to the regime level, where novelty has become more mainstream or resulted in a profound transition. A key barrier is the existence at regime level of “lock-in” mechanisms, which underpin the reproduction of existing ways of meeting transport needs, though some incremental change may occur ([Geels, 2012](#)). However, there are also multiple pathways: [Geels and Schot \(2007\)](#) describe transformation, reconfiguration, technological substitution and de-alignment/re-alignment (see also [Berkhout et al., 2004](#) or [Smith et al., 2005](#)).

Despite the abundance of technological and modal innovation, a transition to sustainable mobility has been slower and more difficult to achieve than in other sectors. With transport’s contribution to climate change at over 25% of the EU-28 greenhouse gas emissions in 2015, it is unlikely that innovative technologies alone will be enough to reach the decarbonization targets set by governments worldwide (see [Marsden et al., 2014](#)). Evidence from research shows that most of the so-called disruptive technologies are not achieving stated objectives of reducing energy consumption or modifying significantly travel behavior. Part of the problem lies in the potential uptake and impact of disruptive technologies in transport planning and transport policy in general, though the wider issue of nontransport social practices should not be underestimated, as highlighted in [Rinkinen et al. \(2020\)](#). For example, simultaneous sharing of smaller vehicles (various forms of lift-sharing) is commonly promoted as increasing sustainability through efficiency gains, but remains persistently unpopular though sequential sharing of vehicles from cars to bicycles to e-scooters enjoys a growing niche following ([Marsden et al., 2018](#)).

The rise of disruptive technologies have, over time, provided challenges to transport planning, and this is primarily influenced by the (cyber) libertarian approach adopted by many of these new technologies and the concerns by some over the underlying principles driving these new technologies and services ([Epstein, 2015](#)). The issues of regulation and the role of government have also been raised, in part, because of the lack of regulation, which has allowed for most of these disruptive technologies to start operating in the transport sector ([Attard et al., 2016](#)). The incumbent transport sector has generally been heavily regulated because of its focus on public infrastructure that support economies and social welfare, as well as for safety reasons. Part of the disruption is also featured in the new “role” of governments and politics to ensure sustainability in planning of future transport systems. So far, evidence of this is scarce, which suggests that further work needs to be undertaken to integrate disruptive technologies (even when they become mainstream such as, e.g., Uber) into the more traditional centralized transport planning systems. There also needs to be a wider public discussion about the role that transport performs in supporting livable places and longer term sustainability in its widest sense, that could inform more holistic appraisal ([Anciaes and Jones, 2020](#)). Concerns about the tendency for traditional

benefit-cost based appraisal to undermine the apparent viability of more sustainable transport investments have been raised consistently for at least a decade (CROSS REFERENCE CHAPTER 10645). More recently, the UK-based cycling charity Sustrans has characterized the issue with existing appraisal techniques as being one that could be resolved by more clearly basing it on a vision that put the least technological/most sustainable modes (i.e., walking, wheeling, and cycling) at the top of a hierarchy of modes, with shared modes and public transport coming next, before car-based modes (Sustrans, 2018).

Conclusions

In this chapter, we have described the concept of transitions, how this applies to the transport sector and challenges incumbent regimes through the potentially disruptive effects of many of the technological developments that continuously emerge in different forms of niche. As the niche innovations are of different types, fostered by different actors, have different rationales and unknown impacts, this creates a challenging environment for transport planning and governance, as many of the affordances of the innovations result in transitions in wider social practices, over which transport planning has no jurisdiction. There is little concrete evidence to understand how scaling-up of innovations affects both sustainability issues (such as social equity, environmental quality, and climate change mitigation) and the viability of existing transport services. There is also a lack of knowledge as to how to model and forecast future transport demand and envision desirable outcomes. This hampers the ability of transport planners to identify which innovations should be encouraged within a finite system as well as how they should be regulated and managed. We have focused only on innovations, which are currently very prominent either on the streets or in the discourse, and have not considered some of the other disruptive innovations that are being mooted or in research and development, such as flying cars, hyperloops or low earth orbit long-haul travel. Of those technologies that are still somewhat “sci-fi,” only autonomous vehicles seem close to realization, but nevertheless the prospect that one or more of these technologies might prove to be “the one” that solves all the problems can tend to distract policy-makers and planners from decisive action in the here and now, falling back instead on traditional solutions, which are often to provide increased road capacity, and often overlooking opportunities to make investments that encourage mode shift (itself a transition) to active travel and existing public transport options due to the limits of the currently available tools for appraising possible interventions.

Introduction

The UK Community Transport Association (CTA), a representative body for providers in the UK, defines community transport in the following way:

“Community transport is about providing flexible and accessible community-led solutions in response to unmet local transport needs, and often represents the only means of transport for many vulnerable and isolated people, often older people or people with disabilities”
(CTA UK, 2020)

Other countries also have services for these groups, but may use different terminology, for example, paratransit in the USA or special transport services in Japan.

Community transport can be described as “formal” flexible transport, in that services are often regulated in respect of vehicles, drivers and operations. This as opposed to “informal” flexible transport, small-vehicle (often unregulated) passenger services with flexible routes, schedule and fares that are a common element of transport systems in the developing world (Wright et al., 2014). Informal flexible services serve a more traditional public transit customer (but confusingly can also be termed paratransit).

Delivery Models and Services Offered

Globally, a range of approaches, or delivery models are used to help those with mobility needs. In the UK community, transport is normally provided by voluntary sector organizations for the benefit of their local community. These organizations typically operate on a not-for-profit basis, with services regulated under UK legislation (the 1985 Transport Act, section 19 and 22), which describes permissible operating regimes. Perhaps the key differentiator between public transport and community services in the UK being the use of volunteer drivers in the latter.

This network of services has grown organically over the years, with little centralized planning or organization, meaning no standard level of provision across the country (this also seen in other countries like Australia). This has led services to develop where there is need, and where there are people looking to serve that need. As a consequence, there are approximately three thousand operators providing services under section 19 and 22 rules in Great Britain (DfT, 2018), with over 15 million passenger trips delivered in England in 2013/14 (House of Commons Library, 2015). In some areas this has meant overlapping services, or different services provided by different organizations. Thus, one settlement might be served by a community minibus to access healthcare as well as a community bus serving trips to shopping and a separate scheme providing mobility for the young unemployed. Rural providers of community transport have additional challenges, needing to deliver their services to a more diffuse population, and over longer distances as facilities and services might be located further from where people live.

Australia also commonly adopts a not-for-profit model based on community need, which provides targeted and flexible services. It has a significant network of community services, which have developed differently in the various Australian states, with no single overriding model or definition. The USA takes a different approach, here services are commissioned by local public transportation companies to supplement fixed-route public transport for the less-able in order to meet equality legislation. These services may be

delivered by private transportation companies, community groups or not-for-profit organizations. The availability (and use) of paratransit services in the US was further boosted by the Americans with Disabilities Act 1990 (ADA), which expressly mandated such an alternative being available. Other community transport-style services using elements of these differing approaches can be seen in various European countries, and in nations such as Canada, Japan, and New Zealand.

In the UK, community transport operators often emerge from local community groups or voluntary sector organizations with concerns for specific groups in society. Operations range in scale from a group of concerned citizens in a rural setting offering a car-based community scheme through to large organizations such as Hackney Community Transport (see <http://www.hctgroup.org/>) in the UK, who provide services in London and several other cities (as well as operating commercial bus services to generate income). Other community services might be operated by local branches of national charities, or by community hubs, which offer a range of welfare and wellbeing services including transport. In other instances, a common journey destination (i.e., a Doctors surgery) might also initiate a service.

Operators of services in the UK (and elsewhere) utilize many different types of vehicles, and deliver solutions in both rural and urban areas. They support journeys for purposes ranging from health and education to employment and social activities. In general, services are demand responsive in respect of routing (although not always in respect of timing), taking people from door to door. Increasingly though this is being supplemented by fixed route and scheduled services, such as community buses (again driven by volunteers). The latter often emerge as replacements to conventional public bus routes that are no longer commercially viable—a particular issue in rural areas.

A key feature of the UK approach is that the organization running the service is acting for social purposes, and not for profit. Conversely, in the USA private transportation companies are often used to deliver services, which can mean high(er) costs per passenger, particularly for demand responsive door-to-door operations. Typically, US paratransit has utilized accessible minibuses (to facilitate wheelchair access), although increasingly providers are now looking to reduce costs by using taxi or rideshare options as an alternative.

Important goals for operators are to help people to stay independent, participate in their communities and be able to access vital services (such as health). As an example, Ealing Community Transport (ECT), a larger UK provider based in London have the following objectives for their services (ECT, 2015):

- To provide accessible transport services for people with disabilities who find it difficult or impossible to use conventional passenger transport.
- To address social deprivation with transport for individuals and groups who may be characterized as socially deprived, for example for people with low income without cars who would otherwise be excluded from the skills development or jobs market.
- To counter geographical isolation through services for individuals and groups who are poorly served by conventional passenger transport networks. For example in rural areas, remote parts of urban estates or areas without transport in the evening or weekends.
- To assist community cohesion through transport for community and voluntary groups enabling them to provide services and to respond to the needs of their community.

The needs identified in these objectives emerge across a wide range of groups within society, who will each have individual requirements to access a wide range of services and destinations. Those countries with limited levels of funding for community-style services may at times have to focus on more specific groups of people or particular journey purposes—that is, access to healthcare in some UK services. This has meant the frail and disabled in Australia for example (Mulley and Nelson, 2012), whilst US paratransit has concentrated on those with problems accessing public transport, who are unable to navigate or access the public bus system, or have a temporary need for mobility following injury or a limited duration disability. Services in Japan also focus on the elderly, and the less-able, but importantly, in rural areas they may also provide transport for the public, to make up for shortfalls in scheduled public transport (Wright et al., 2014).

Funding of Services

UK community transport relies on volunteers to perform driving and sometimes administration roles, but looks to central and particularly local government, or other organizations for financial resources to purchase vehicles and to operate services. The latter has included Parish councils (neighborhood-based administrations with limited powers and resources), and doctors' surgeries who see benefits for their patients. Local communities may fundraise to support services, and commercial organizations may sponsor or fund new vehicles as part of their corporate social responsibility (CSR) activities. Passengers will also typically pay a small distance-based fee for the journeys they take and an annual membership or registration fee in order to access the service. In some instances, passengers will be able to use concessionary passes that offer free travel on public transport to cover their travel costs.

State or government funding is commonplace in services across the world, but may take different routes to service operators. Prior to 2018, the Australian government provided direct funding to operators for community transport services. This has now changed to a system whereby government monies fund individuals' who source and pay for transport from a personal budget (Mulley et al., 2018). Australian operators are not permitted to charge fares, but may accept donations from passengers (Mulley and Nelson, 2012). Services in Japan are reliant on local authority subsidy, and as noted above may subsidize routes by carrying other passengers in some instances. US paratransit services are funded by local public transportation agencies, and may charge fares (up to twice the equivalent public transit fare is allowable).

Larger UK operators may also operate commercial services to cross-subsidize community operations. This could be minibus services for education, or health and social care services for a local authority accessed through commercial tender and bid processes, or by operating traditional local bus services. In all instances, these operations are run with paid staff, as if they were a commercial company, with strict demarcation between the two parts of the organization. Operators may also offer their vehicles for private hire outside of operating hours, to again subsidize community services. The scale of larger operators does provide economies in respect of costs of administrative staff, depots and technology, but does risk breaking the link between the service and the community it serves.

Countries that make extensive use of volunteers (like the UK), can minimize the costs of running a service, but this then creates a problem of recruiting enough volunteers. Many volunteers are themselves older people, and more likely themselves to be constrained by health issues and their own ability to access and use transport. This seems to be less of an issue in some other countries, with Australian services seemingly able to draw from a wider age range (Denmark and Stevens, 2016). The use of commercial operators in the US helps to avoid this problem there.

Evidence of Benefits

Studies of community transport in the UK claim a range of benefits, which are likely to be replicated in services in other countries. For example, the access to mobility it provides is seen to be of significant importance in tackling isolation and promoting social inclusion (Canning et al., 2015). Interactions with the driver can become “*very significant and something to look forward to*” for those whose opportunities for social interaction are limited (Martikke and Jeffs, 2009). Several studies have looked to quantify these benefits monetarily in respect of loneliness and social isolation, with one proposing that community transport could save the UK National Health Service (NHS) between £0.4bn and £1.1bn a year in related costs (Deloitte and Charity, 2015).

Community transport can also play an important role in tackling poor accessibility by providing services when mainstream transport is not viable (Canning et al., 2015). Even if there are alternative public transport services available, reaching a stop may be problematic. It may be too far from a person’s home, there may not be a footway, and there may be no street lighting or benches to take a rest. Taxis could provide door-to-door services, but many see them as expensive, and the driver’s responsibility only comes to the kerbside. Community transport volunteers will often address what might be termed the last 10 yards/m, and collect and return people from and to their homes.

Public transport and particularly taxis may not be suitable for the disabled, unable to carry a wheelchair for example, whereas vehicles used by community transport are usually accessible, and drivers will have received training in supporting such passengers. This can facilitate independence, and counters transport-related social exclusion for (older) people with limited mobility, who may not be able to leave their house otherwise, and for those with disabilities who lack accessible transport. Some users would not be able to live independently without community transport and would need to relocate, or move into a care setting (DHC & TAS, 2011). Community transport also provides people in rural areas with access to key services (Canning et al., 2015), helping to maintain rural communities. There are economic benefits, allowing people to go shopping and access employment, and community transport can help build social capital in communities (ECT, 2015).

Where community transport services are delivered by voluntary organizations they may also provide further social benefits. Drivers and the organization they work for are operating the service for the benefit of the people and groups they are carrying, and therefore are likely to have a more positive attitude to their passengers. Through regular contact, they will also develop relationships with passengers that will directly address issues such as isolation and loneliness, in effect providing a form of befriending service for passengers.

Several health benefits are seen from the use of community transport. These include earlier detection and treatment of health conditions and thus significant savings for the UK health service (Age Scotland, 2013), as well as facilitating people to get out more, and be more active (Canning et al., 2015). Perhaps most importantly, the use of community transport for health-related journeys is linked to a reduction in the number of missed medical appointments (termed “Did Not Attend” or DNAs), which can be a significant cost to health services (Countryside Agency, 2014).

Because benefits are seen across a range of policy areas, comprehensive measurement can be difficult, and as a result several studies have looked to the ‘social return on investment’, (SROI) methodology (Cabinet Office, 2009), and this is becoming a more commonplace approach to quantify benefits of community services. Others have considered the costs of replacing community transport with commercial transport, suggesting the resultant costs would be an order of magnitude greater than current local authority spending in the areas studied (DHC and TAS, 2011). This in part because community transport delivers more than just mobility.

Challenges Facing Community Transport

Whilst the evidence above suggests significant benefits come from community transport-style services, there are also important challenges facing provision worldwide. Foremost amongst these are growing demand and the need for sufficient funding, problems exacerbated by a decade of austerity measures in many countries.

Funding

Community transport in the UK is primarily funded via the state, through local authorities at a town, city or county level. Reductions in central government funding to these bodies over recent years has led to cuts in local services such as community transport. In some locations, this has meant a rationalization of operators and their services. In recent years, small amounts of capital funding (to purchase vehicles) have come from central government, but crosssubsidy from commercial or commissioned services remains a key source of revenue funding. This can put community transport services into direct competition with commercial providers, who may perceive an unfair advantage in respect of costs for operators using volunteers in parts of their business. This has led to lengthy legal disputes in recent years in the UK and remains a contentious issue.

Funding approaches are also changing, with some countries exploring the use of a person centered funding (PCF) model. This gives “clients” a budget to purchase mobility along with other services they require. This could mean that current block budgets to providers become fragmented across different types of service (e.g., some people may choose to use taxis or rideshare services if they are comfortable with doing so, and perceive a comfort or time benefit). This might mean changes in business models for community operators and potentially puts clients at risk of not being able to access mobility (CTAUK, 2018). The PCF model has been implemented recently in Australia, but at present other countries (such as the UK) have not yet taken such an approach.

Meeting Demand

Current services may struggle to meet demand, which generally exceeds supply, so that some clients miss out and others may get limited access to services. Women currently outlive men, but older women are less likely to drive (often through lack of confidence) meaning growing numbers of older women are looking to community services for their mobility solutions. Ageing populations also mean more older people with chronic health conditions that may preclude other modes of travel, and necessitate additional health-related trips. More generally, medical appointments can necessitate long journeys (particularly in rural areas), and be time consuming, meaning some operators may need to ration such trips. In Australia a shift to older and frailer clients (aged 80-90) has implications for the nature of services that have to be provided (Battellino, 2009), perhaps making them less efficient as well.

There are also supply-side constraints facing operators, who must maximize the use of their vehicles by aggregating as much demand as possible. Thus, it may be that there are conflicting demands for transport to healthcare and shopping at the same time, potentially disappointing one or other set of users. Commonly minibuses are used as transport, but they may only be carrying a small number of passengers in a 16-seat vehicle, an inefficient use of resources. Prioritizing service delivery then becomes important, raising questions as to what purpose is more important (healthcare or shopping for example). This can create issues in respect of when will a journey actually be confirmed for a user? What if greater demand emerges later, will already confirmed routes then be re-arranged for example? There is also the issue of whether there is sufficient funding to pay for routing and booking systems for this growing demand.

Operational Issues

Community transport in all countries also has to deal with a range of operational issues. For example, there are inconsistencies in service quality and service provision across providers in the UK and elsewhere. In recognition of such issues, the UK government has provided some limited funding to try to improve standards and service levels. In Australia, the establishment of accreditation and operation standards were seen as a response to similar issues (Battellino, 2009), whilst greater co-ordination of vehicle use to avoid duplication and underutilization of transport resources has been proposed in the US (TCRP, 2004). Many of these issues are potentially addressed with new technological solutions (e.g., booking and routing systems), but these can be expensive, and beyond the reach of many smaller operators.

Looking to the Future

Several developing and emerging trends will affect the need for community transport services in the future, including population ageing and health trends, new technology and sector and government responses to the climate emergency.

Drivers of Growing Demand

A key user group for community transport are the elderly, and their numbers are growing globally (UN, 2017). The overall number and proportion of older people in populations will both grow in coming decades. With increasing life expectancy, this also means that there are greater numbers of those in their eighties and nineties, a group more likely to have physical and cognitive issues that impinge on their mobility. Notwithstanding growing car use by this age cohort, more people will be unable to use a car because of health constraints. These might be health issues related to the normal processes of aging (declining eyesight, personal mobility and cognitive decline) alongside the health outcomes of more widespread longer life (e.g., dementia). All of these factors suggest greater future demand for “public” transport, and specialist services for older people. This at the same time as countries like the UK have seen a decrease in the availability and supply of public transport over the last few decades as public funding has diminished, and commercial viability of services has become increasingly difficult.

New Transport Solutions (Technology and Operating Models)

One of the key changes in transport in recent years has been the arrival of new technology, in particular the Internet and smartphone. This has revolutionized the way in which many people access information about travel, and purchase their tickets. Those who will be older people in coming decades are experiencing and adopting these new technologies, and will likely expect them as services in their later life. These developments have also enabled the growth of rideshare (through Transport Network Companies - TNCs), offering almost instantaneous mobility, at seemingly affordable prices. Alongside near real-time delivery from other Internet-based companies, developments such as these are creating a new expectation in service levels.

Paratransit services in the USA have developed sophisticated technological solutions in response to the demands of providing services that meet the legislative guidelines. Similar solutions for scheduling, routing and booking are now in use in the US and Europe. The costs though can prove prohibitive for smaller organizations providing community transport. The use of digital technology is seen as a means to meet challenging demands in transport, helping with efficiency, lowering costs and optimizing operations. Greater use of technology is not without risk though, and there are concerns that reliance on technology risks losing human contact with passengers.

The concept of mobility as a service (MaaS), where multiple modes of transport might be combined by travelers and commoditized as a product may also be relevant. There is potentially a role within MaaS for community transport to become another element in wider public transport networks and services. This might offer opportunities to commercialize surplus space on community transport-e.g. selling spare seats to other travelers who would not qualify as users, or to buy “community miles” on public transport services. It would facilitate development of services nationally (or greater homogenization). MaaS could bring economies of scale and more effective booking systems. It might allow for greater use of vehicles, reduce empty seats, and make the best use of volunteer time. One risk might be the loss of the “local” nature and personal touch of services. The MaaS approach might provide a way for community operators to adjust to person centered funding, offering a wider package of mobility choices, and allowing clients to choose from them to meet their needs (Mulley et al., 2018)

Responding to the Climate Emergency

Globally there needs to be radical change in transport, including a move to shared mobility to help reduce the impact of the transport sector (around a quarter of all UK emissions are transport related - DBEIS, 2020). This may have positive benefits for community transport, as it already provides a model for how local transport can respond to mobility needs. It is possible to see how a more extensive network of shared, local demand responsive transport services would offer a more efficient transport solution in response to the need to reduce emissions significantly over the coming years.

Conclusions

Community transport services are highly valued by users, but operators can struggle to meet demand. This situation is likely to persist, and potentially worsen as trends in demographic change and the transport landscape increase future demand. Some new models of operation may be helpful, and there may be lessons to learn from other new entrants to the transport landscape in recent years-in particular their use of technology. There are also risks here though with concerns about digital literacy of older people, and digital divides between the younger and older old. Looking forward 30-40 years, it may be that the much-heralded arrival of driverless vehicles will offer a solution for those who need community transport. Until then there are patently benefits to be gained from adequately funding the existing community model to meet the growing demand for services.

Glossary

Autonomous delivery vehicles are electrically powered motorized vehicles that can deliver items or packages to customers without the intervention of a delivery person.

Crowdshipping involves persons who are already traveling carrying parcels, using their spare carrying capacity in vehicles to carry parcels for other people.

Logistics is the function which ensures the right materials, right quantity, right quality, right place, right time, right method, right customer satisfaction and right cost.

Parcel lockers are locker banks that allow receivers to pick up goods, as well as carriers to exchange goods between modes.

Supply chain is the mechanism which guarantees that products or services go from an origin point to a destination, passing through various stages, including transformations, storage, and transportation.

Urban goods distribution is the process which ensures that the resources needed in urban areas are positioned in the right places, at the right times, in the quantity required and at a certain cost, whilst not neglecting the interests of the main stakeholders involved.

Introduction

The movement of goods generates conflicts with other functionalities within the urban structure. In recent years, this conflicting interaction has intensified its impacts on urban environment, thanks to the increase of flows to be delivered to the city center through growing diversity and complexity of delivery channels and processes. The intensity of said impacts lead to pressure placed by society on freight and logistics-related activities to perform the operations based on a “negotiated balance” with environmental protection, economic growth and social equity. Such pressure has sought to influence the industry perspective, where the goals are related to cost imperatives and service objectives such as the maximization of delivery frequency, avoidance of split consignments, maximization of vehicle load, reduction of the mileage traveled and reduction of the overtime payments to drivers. The integration of environmental protection and social equity issues into freight and logistics-related activities has been publicly scrutinized by society, as far as the minimization of disturbance, congestion and pollution that are frequently associated with freight movements in urban areas are concerned. The importance of this scrutiny is such that it has contributed to the definition of determinant drivers for the development of research on emergent logistics processes and services.

In such a context, it is noticeable that research carried out on the topic of logistics and transport planning has strongly reflected concern with the impact on sustainable urban development. Studies embracing an environmental perspective have focused on freight solutions that might contribute to an improvement of the urban environment quality: that is lower environmental impacts, less noise, and less congestion. Research projects that have adopted an economic perspective have tried to find solutions to optimizing the transport of goods into the city, while minimizing the number of trips, maximizing companies’ profits and avoiding congestion periods. Similarly, research work focusing on societal equity has been dedicated to maximizing the efficiency of all systems, mitigating the negative impacts associated with urban goods distribution activity and thus, promoting mobility and sustainability within the system. When seen together, these different perspectives and respective goals reflect the aim of designing environmentally friendly and efficient distribution systems to supply the urban centers, while endeavoring to integrate the main (and sometimes conflicting) perceptions of society and companies.

The design of systems that are simultaneously efficient and environmentally friendly is anything but straightforward. It requires balancing a complex system of variables and stakeholders in a struggle for the use of scarce territory with a significant demand in terms of correlated functionalities. With the emergence of Industry 4.0 and its side effects, the current unresponsive prospects toward those systems can be significantly reversed. Further comprehensive reviews on the Industry 4.0 and overviews of its indissociable and challenging concepts of Internet of things, cyber-physical systems, Big Data, cloud computing, mobile-based systems, social media-based systems can be found in [Maslarić et al. \(2016\)](#); [Hofmann and Rüsch \(2017\)](#); [Trappey et al. \(2017\)](#); [Barreto et al. \(2017\)](#). For the purpose of the scope of this article, the Industry 4.0 paradigm creates value from information that is extracted and refined from data, which enables mass customization, the possibility of free flow of data within processes and services and opportunities for incorporating logistics and transport planning solutions within smart city technological initiatives.

In this article, fundamental concepts arising from the most recent societal trends and industry changes will be looked at. This article, makes explicit the interpretation and implications of the visions assumed by the concepts. The concepts are by no means unambiguous; there is not one uniform approach and no single general application of the concepts and it is doubtful whether such a thing would–could or should–ever exist. The definition of the concepts is highly dependent on the specific context and can serve different users with different priorities and concerns. These concepts constitute determinant guidelines for keeping abreast of the most likely developments in the short term.

Accordingly, this article explores the opportunities for the introduction of some emerging concepts in freight transport and urban goods distribution-related activities. This research is exploratory, and the main contributions inform and provide insights for developing policies, plans, or initiatives to create efficient and environmentally friendly distribution systems.

The following sections present the interpretation the concepts assume and correlate them with the emerging trends in urban freight transport and goods distribution.

Urban Goods Distribution and Transport Planning

The concept of “urban goods distribution” is closely correlated with the concepts of “supply chain” and “logistics”, both in terms of content and formal context.

Supply chain encompasses efforts involved in producing and delivering a final product or service, from the supplier’s supplier to the customer’s customer. There are few companies that can produce end products for end-customers from raw materials on their own, without the assistance of other organizations. The company that produces the raw material is often not the same company that sells the end products to the end customer. In order to provide end products to the end customers, a network of actors is involved in activities (such as purchasing, transforming, and distribution) to produce products and/or services. The series of companies (actors) and respective processes that interact in this producing and delivering process through the flow of products, the flow of information and the flow of money, is named supply chain.

With the growth of the Internet of Things, on the basis of predictive management tools, one can envisage in the short term an increasingly important role for the information flows as the main supportive driver of supply chain processes and services. The value of the information flow will be reflected in terms of performance, scalability, robustness, and flexibility in freight and logistics processes and services.

Supply chain is the mechanism which guarantees that products or services go from an origin point to a destination, passing through various stages, which may include transformation, storage, and transportation.

Logistics is a transversal function that exists in all structures, sometimes in more obvious ways; it works as the integrated system that brings the necessary processes, activities and logistic resources to materialize the supply chain into relation with each other. This means that logistics is what ensures that products pass all the stages in an effective way and arrive in accordance with the required conditions. The Council of Logistics Management (2020) defines the concept as “the process of the supply chain of planning, implementing and controlling the efficient, cost-effective flow and storage of raw materials, in-process inventory, finished goods and all the related information from the origin point until the consumption point, considering the service requirements of customers”. It is a less visible function that ensures the good functioning of the supply chain. The article defines logistics as the function that contributes to the creation of time, place and even form through the process management that allow companies to get the right goods to the right place at the right time, in the right conditions and at the right cost.

Logistics is the function which ensures the right materials, right quantity, right quality, right place, right time, right method, right customer satisfaction, and right cost.

When logistics activities are carried out in urban areas, they reveal unique characteristics that make them different from general logistics activities. For this reason, freight and logistics-related activities in urban areas are usually labeled specifically as “city logistics”, “last mile,” or “urban goods distribution”. Everything that is consumed in urban areas or the materials used in industrial processes brought by the urban goods distribution system. The urban goods distribution system differs from long haul and other freight transportation segments ([Jaller and Pahwa, 2020](#)). Urban goods distribution refers to the last step taken to move and store a product from the supplier stage to a customer stage in the supply chain; accordingly, it deals with much more complex network environments. It differs from general logistics to the extent that urban goods distribution is an activity that optimizes the logistics and transport activities by private companies while taking traffic congestion, energy consumption and environmental damage within the framework of a market economy into consideration. Most definitions of the concept imply that the distribution activity is closely related to and even dependent on, transports and highlights the need to balance private companies’ aims and societal concerns. It

concentrates mainly on goods transport but, as supported by [Muñuzuri et al. \(2005\)](#), the concept can also include service vehicles (inspections, installations, technical service, and emergencies) and other commercial uses (sales representatives, company cars).

The electrification, automation, and shared mobility transformations constitute promising alternatives for improving the efficiency of last mile operations, particularly in terms of reduction of costs, time, and carbon emissions. Consequently, the number of initiatives that incorporate automation and electrification in the last mile in recent years has significantly grown, some of them with a considerable level of market readiness, while others still require more research. The advent of these technologies is imminent, but there are still barriers that do not allow for their wide diffusion, despite their potential benefits.

Urban goods distribution moves goods to the final customer, using a transport system and giving rise to social, environmental, and economic/financial impacts. It is defined as the process which ensures that the resources needed in urban areas are positioned in the right places, at the right times, in the quantity and quality required and at a certain cost, whilst not neglecting the interests of the main stakeholders involved.

Sustainable Mobility of Goods

People use a transport system to satisfy their needs and mobility is a derived need which surfaces when basic human needs and related activities cannot be satisfied in one place. A transport system affords the individual the possibility of traveling, and thus from a transport planning point of view, mobility measures how well the transport system fulfils its purpose, providing the individual with the possibility to participate in spatially based activities. Thus, mobility takes place to fulfill specific plans and projects, through a physical and/or virtual movement, and is influenced by several elements, such as lifestyles, spatial characteristics, and accessibility. All ingredients are generally given only if there is adequate means of moving people, goods, and ideas. Thus, greater mobility means increased quality of life for the individual (greater freedom to choose activities and greater amount of time to dedicate to them). In this sense, mobility plays a key role in development and depends essentially on the means enabling one to move. This definition, common to most publications on mobility, is generally applied to passengers. Indeed, little has been written, and is known, about mobility for freight transport compared to passenger transport; thus, much fewer studies focus on sustainable freight transport mobility. This lack is due to the restricted availability of data concerning freight transport but is somewhat attenuated by the fact that mobility concepts and indicators used for freight transport can be relatively similar to the ones applied for passenger transport.

Adapting the definitions presented above to the particular topic of logistics and urban goods distribution, “mobility” is the ease of movement, dependent on an (efficient) transport system and a diversity of (sustainable) options to get to a final destination, where the consumption needs are met at moderate costs to transporters and to society and as close as possible to the planned times (reliability).

Emerging Urban Goods Distribution Trends

With the emerging requirements of Industry 4.0, of which the Internet of Things is just one of its offshoots, it is expected that fleet management operations will go through substantial changes in the short term ([Ahani et al., 2016](#)). **Autonomous delivery vehicles** are electrically powered motorized vehicles that can deliver items or packages to customers without the intervention of a delivery person. Autonomous trucks, autonomous robots, or even drones have been tested for last mile delivery of goods in urban areas. Currently, their market is growing rapidly and is very dynamic ([Figliozi and Jennings, 2020](#)). It is expected that due to the emergence of flexible manufacturing systems, the rising demand for customized autonomous delivery vehicles and the adoption of industrial automation by SMEs, the landscape for autonomous delivery vehicles will evolve fast.

Current systems are well known and widely implemented in manufacturing, medicine, and logistics. In these systems, the fleet is organized in a centralized way. Tasks like motion planning and allocation of tasks are done by a central entity. However, driven by future requirements such as flexibility, robustness, and scalability, the current trend is toward the distribution of the total intelligence of a system to its components: each device gets a part of the total intelligence, so as to be able to operate independently, in an endeavor to achieve the same global goals ([De Ryck et al., 2020](#); [Killeen et al., 2019](#)).

The benefits of autonomous delivery vehicles can include cheaper delivery costs for businesses, faster service to customers, energy conservation and sustainability, safety for delivery personnel, and accuracy in delivering the right package to the right customer. Despite the fact that there are numerous studies on the mechanical, electrical, and computational design of robots ([Figliozi and Jennings, 2020](#)), academic publications studying the impacts and implications of autonomous delivery vehicles for last mile logistics are few and far between. Examples of such research work is [Vleeshouwer et al. \(2017\)](#), who studied a small robot delivery service, showing that costs can be reduced significantly, but that the robot capacity is low and that robots are not economically feasible. [Jennings and Figliozi \(2019\)](#) also analyzed the regulation and characteristics of sidewalk and road autonomous delivery vehicles in the USA, with the results showing that footpath autonomous delivery vehicles can provide substantial cost, time, and vehicle travel savings.

From a literature review and reports on the use of these solutions in experiments and initiatives, one can agree that autonomous delivery vehicles can be feasible if companies scale up or cooperate to increase robot utilization. When compared with a conventional delivery van with a human driver, autonomous delivery robots are also more economical when delivery routes are relatively short, and their limited mileage range is not a restriction. Given the fast pace of technological development, it is expected that autonomous delivery vehicles will experience significant improvement in terms of their development and implementation in the short and medium term.

While companies are adapting their fleet management activities to the emergence of autonomous delivery vehicles, cities are providing solutions such as parcel lockers. **Parcel lockers** are locker banks that allow receivers to pick up goods, as well as carriers to exchange goods between modes. Parcel lockers are located near residences, offices, public transport terminals, and shopping centers. Some cities, such as Lisbon (Portugal), also locate them in underground parking areas with surveillance cameras that ensure easy loading and unloading operations as well as security conditions. Trucks and vans can be used to carry parcels to locker banks, and these can also then be picked up by couriers for delivery to the final customers within the respective area. These infrastructures can play a significant role in minimizing home delivery trips, as they provide an effective and reliable option for online shoppers.

Parcel lockers are expected to increase the efficiency of urban goods distribution activities and, simultaneously, to contribute to achieving a more environmentally friendly process. Whether operated by single carriers or multiple ones, reductions in financial costs (vehicle operations), emissions and congestion are expected to be achieved in the short term.

Lastly, to introduce a nonphysical trend, the **crowdshipping** phenomenon is also worthy of mention. Crowdshipping involves persons who are already traveling carrying parcels, using their spare carrying capacity in vehicles to carry parcels for other people. Crowdshipping has a significant potential for reducing the number of freight vehicles operating in urban areas and reducing the operating costs for carriers.

This mechanism, which still has security, and liability-related issues that need solving, can be supported by the use of allocation methods or apps that match travelers' routes with delivery requests. There is a strong complementary potential when this system is used together with parcel lockers to achieve the design of more effective and environmentally friendly systems.

Conclusions

As with other initiatives and solutions that rely on combining sharing urban infrastructures with the intrinsic profile and needs of personal and commercial drivers, as the one provided in Melo et al. (2019), the emergent concepts mentioned in this article can contribute to achieving a negotiated balance between industry and research. These concepts by no means represent the only way of achieving efficient and environmental friendly urban goods distribution systems. The selection of concepts was based on the provision of a general overview of the subject matter plus the presentation of emerging trends and their particular potential dissemination in the short to medium term, and the respective implications. Further research and context must be explored, for instance, taking unusual events like pandemics, security rules, and the provision of unmanned health care into consideration. Parcel lockers and autonomous delivery vehicles, as well as voluntary crowdshipping, are initiatives that can play a relevant role when those events take place, but additional trends should also be explored in detail.

Biography

Sandra Melo (Ph. D.) currently works at CEiiA (Center of Engineering and Development, Portugal). She has a consolidated experience in the assessment of mobility solutions, with a major focus on investigating the performance of last mile "best practices", taking both public and private stakeholders' objectives into consideration. She has coordinated and developed R&D projects on the evaluation of the impact of new modes, services and mobility systems, integrating KPIs for traffic, energy, environment, operational, and economic targets. She also has an extensive experience as a consultant on transport policy and planning, a technical coordinator of national and international projects, both in academia and the industry, and a trainer and lecturer on sustainable freight transport, transport policy evaluation, and transport behavior. She is the author of scientific papers on the topic of the sustainable mobility of passengers and freight and has been awarded four times competitive nominal prizes in recognition of her scientific contribution to academia. She is also co-chair of Cluster 3: Logistics and Freight of the NECTAR scientific network and chair of the Portuguese Transport Studies Group (GET).

Introduction

There is good evidence that the average distance traveled per person by car in many developed economies ceased to grow towards the end of the last century. This phenomenon has been termed "Peak Car", by analogy with "peak oil", which refers to the expected peaking and decline in output of this finite resource (Goodwin and Van Dender, 2013). However, for car use, the evidence points to a cessation of growth as the prime effect, with possible long-term decline not yet generally apparent. Accordingly, the term "Plateau Car" has been proposed to designate the phenomenon (Metz, 2013a).

Evidence for Plateau Car

National travel surveys commissioned by governments are an important source of data on travel behavior. Time series data for three key parameters from the English National Travel Survey are shown in Fig. 1 (NTS, 2018; Table 0101). The average distance traveled by all modes (other than international travel by air) increased from 4500 miles per person per year in the early 1970s to reach 7000 miles around 2000, falling thereafter and stabilizing at about 6500 miles in recent years. Three quarters of this distance is currently traveled by car, driver and passenger together; car use per person has declined somewhat since 2002 (Fig. 2).

The US National Household Travel Survey found growth in average daily travel by all modes increasing from 25.1 person miles in 1983 to reach 40.2 miles in 2001, growth then ceasing (39.0 miles in 2017) (NHTS, 2017; Table 14). Average distance per person traveled by private vehicle was 30.85 miles in 1990 and 30.45 miles in 2017 (NHTS, 2017; Table 12).

Data for distance traveled by car per capita in 11 developed economies are shown in Fig. 3, estimated from official statistical sources for total distance traveled by car and for total population. Car use grew until around the turn of the century, when it stabilized or fell in all but one case (Poland). Millard-Ball and Schipper (2011) found evidence for a leveling out or saturation of total passenger travel since the early years of the 21st century for eight developed countries.

Demand Saturation

Cessation of growth of demand for a product or service is a common feature of all markets. A new product that offers benefits to users is taken up, initially by early adopters with the more cautious following later. High levels of ownership, as for instance found with many household appliances, characterize a mature market in which growth has substantially ceased and demand is said to have saturated. It is plausible that the cessation of growth in surface travel and car use reflects demand saturation for daily travel for the purpose of gaining access to a wide choice of destinations offering services and opportunities.

The growth of average distance traveled in the last century shown in Fig. 1 is a consequence of an increase in speed, given the unchanged average travel time over the period, and is largely attributable to growth of car ownership. Conventional economic appraisal of transport investments that result in faster travel assumes that the main user benefit is the saving of travel time [10011, 10097]. However, the observed invariance of travel time implies that the main benefit is better access to desired destinations and the associated increase in opportunities and choices [10045]. Access is subject to diminishing returns as choice and opportunities increase. However, access also increases with the square of the speed of travel, being proportional to the area of a circle, the radius of

Figure 1 National Travel Survey. Source: *NTS, (2018) Table 0101*.

Figure 2 Distance traveled by car per person (driver and passenger). Source: *NTS, (2018) Table 0303*.

which is proportional to speed. This combination of diminishing returns while increasing with the square of speed yields a saturation function.

There is some evidence in support of the relevance of saturation in explaining cessation of growth of per capita car use. **Fig. 4** shows the proportion of households in England owning one or more cars, which increased steadily until the end of the last century when growth ceased, suggesting both saturation of demand for car ownership and the main cause of the cessation of average distance traveled by all modes of travel [10452].

UK data on access to key services by journey time indicates high proportions of potential users having access within reasonable travel times. For example, for access to family doctors (termed General Practitioners, GPs), 71% of users are within 15 min travel time by public transport/walking and 96% within 30 min, while 87% are within 15 min by bicycle and 98% by car (*JTS, 2017*; Table 0201). Similar high levels of access are found for other services, including employment, schools, food stores, and town centers.

Figure 3 Distance traveled by car per person. Source: Dr Kit Mitchell, from UN ECE Transport Statistics for total distance traveled by car and official population statistics for total population.

Figure 4 Proportion of UK households owning one or more cars. Source: NTS, (2018) Table 0205.

Journey time statistics can be used to infer levels of choice of key services. For instance, the populations of a majority of English localities have access on average to five or more GPs within a 30-min journey by public transport/walking, and almost all localities have such choice within 15 min by car (Metz, 2013b). A study of access to supermarkets in Britain found that 80% of the urban population had access to three or more large stores within 15 min by car, and 60% to four or more (Metz, 2010). Such high levels of access and choice are consistent with the proposition that demand saturation is contributing to the cessation of growth of per capita car use. In the case of supermarkets, this has come about through (1) the growth of car ownership and (2) the supermarket chains taking advantage of road construction that made land accessible for new large stores on the edge of urban areas, both trends now largely played out. Although comparable data for other developed economies are not available, it seems likely that similar saturation phenomena are occurring.

Demographic Change

There are a number of demographic changes that are contributing to the cessation of growth of per capita car use (Metz, 2016). Movement of populations from country to city is a long-term global trend, reinforced in recent years in developed economies by the shift from manufacturing to business services and the “knowledge economy” that prefers to locate in city centers. Contributing to urbanization is the process that economists term “agglomeration”, which offers particular advantage to the business services sector. Concentrations of firms in one geographic area benefit from learning, sharing, and matching. Firms acquire new knowledge by exchanging ideas and information, both formally and informally; they share inputs via common supply chains and infrastructure; and they benefit by matching jobs to workers from a deep pool of labor with relevant skills. Agglomeration leads to urban development and population growth at higher densities, despite the high land prices, rents and other costs. This growth has increased congestion on the urban road network and so made car use less attractive, but at the same time has improved the economic viability of public transport (Metz, 2019).

The growth of the economy in cities, as well as the expansion of city center universities, has attracted young people to move to vibrant cities to study, work, and live. This has contributed to a significant change in travel behavior amongst young people in developed economies. A recent comprehensive review of the research evidence and survey data noted a trend since the mid-1990s for successive cohorts of young people (ages 17–29) to own and use cars less than their predecessors (Chatterjee et al., 2018) [10429]. This contrasts with the baby boomers, born from 1946 to 1964, who led a rapid, prolonged and persistent growth in car ownership and use.

Factors contributing to this trend away from car use include the cost of car ownership (not least, high insurance charges for younger drivers), problems of parking in cities and on campuses, and the viability of alternatives such as bicycles, public transport, shared car use, and smart-phone apps to summon a taxi. However, according to Chatterjee et al. (2018), the main causes lie largely beyond the transport system and include increased participation in higher education, for which the car is not part of the lifestyle; the use of digital communications and social media; and more generally a delayed transition to what was traditionally seen as adulthood—commitment to a career, getting married, home ownership, starting a family, with stable employment a strong determinant of being a car driver.

An important question is how this shift away from car use by young people will affect the way they travel as they get older. Stokes (2013) has shown that those who start to drive later drive less when they do start; for instance, for those now in their thirties in Britain, if they learnt to drive when age 17, now drive 10,000 miles a year on average, while if they learnt at age 30, they are likely to drive around 6500 miles a year. This reduced mileage seems likely to reflect greater experience of alternative modes to the car gained before learning to drive, as well as living in places where such alternatives are viable, in particular for journeys to work. Chatterjee and colleagues concluded that while there are many uncertainties about the travel behavior of future cohorts of young people, as well as about how this may change as they get older, it is nevertheless hard to envisage realistic scenarios in which all these uncertainties combine to re-establish earlier levels of car use.

‘Peak Car’ in Big Cities

The discussion thus far has focused on per capita travel demand. Population growth is, of course, an important determinant of total travel demand. The impact of urban population growth on car use is well illustrated by the experience of London, for which exceptionally extensive travel statistics are available (TfL, 2019). After a period of population exodus, when inhabitants left poor-quality, overcrowded housing for a better life beyond the city boundaries, decline reversed around 1990 as the built environment improved and agglomeration economics increased productivity, generating higher incomes. The population of London increased quite rapidly, from 6.8 million in 1991 to 8.9 million in 2018.

Despite this population growth, road vehicle traffic in London as a whole, about 80% of which is car traffic, has not increased over the past 20 years—indeed has fallen by about 10% (Metz, 2015; TfL, 2019, Table 9). This is due largely to the limited capacity of the road network. Plans were proposed in the 1960s to build more roads to accommodate the expected growth in car use. An initial section of elevated motor road was constructed westwards from central London, but this was seen as damaging to the urban fabric and plans for similar new roads around central London were largely abandoned. Thus London has essentially retained its historic road network, which has constrained the growth of traffic. Indeed, there has been a reduction in the capacity of the road network for cars as the result of reallocation of road space to bus and cycle lanes and pedestrian uses.

Given that London’s population has been increasing but car traffic has fallen, it follows that the share of journeys by car must have declined, as is indeed observed. In 1993, when the relevant data series starts, 50% of all trips in London were by car (driver and passenger), but this declined to 35% in 2018 (TfL, 2019; Figure 2.3). Over the same period, the share of walking trips held steady at 25%, while cycling grew from a low base to reach about 3% of all journeys. The decline in car trips was compensated by the growth in use of public transport, which currently account for 37% of all journeys.

Fig. 5 shows an estimate of the share of journeys by car in London in the century 1950–2050, based on historic data, Transport for London’s recent data mentioned in the previous paragraph, and future extrapolation that takes account of projected population growth and assumes no addition to road capacity but continued investment in urban rail. From 1950 car ownership and use grew while at the same time the population was falling. Car use peaked at 50% of all journeys at around 1990, the time when the decline in population reversed. As the population subsequently grew, the historic road network acted as a capacity constraint, which meant that the share of trips by car had to fall, a trend projected to continue out to 2050, when some 27% of trips would be by car, on the stated

Figure 5 Share of journeys by car in London, 1950–2050. Source: author's estimates and *Transport for London* (Metz, 2015).

assumptions. The Mayor of London has more ambitious plans, aiming to reduce car use to only 20% by 2041, driven by concerns about health impacts (Mayor, 2018).

What is shown in Fig. 5 is the clearest illustration of the concept of “Peak Car”, a peak followed by decline in the *share* of trips by car. This has been termed “Peak Car in the Big City”, to distinguish it from peak or plateau car, referring to the distance traveled per person as discussed above (Metz, 2015).

While London provides the best data sources, there is evidence for a similar phenomenon in other large cities. A substantial study identified a peaking of car use in terms of car trips per day in Paris, Berlin, Vienna and Copenhagen, as well as London; on the other hand, data from US cities indicates a continuing very high level of car use (Jones, 2018). There is supporting evidence of a decline in car traffic in a number of UK cities, particularly in their centers, including Manchester and Birmingham (Metz, 2013a), as well as in the major Australian cities (Newman and Kenworthy, 2011).

A broad distinction may be made between cities with historic central areas where the street pattern limits car use and the population density make public transport economically viable; and more recent cities built at low density with the car in mind as the main means of mobility. This distinction is broadly between European and North American cities, although with central parts of the some of the latter having high density, and suburbs of most generally being of low density. The available evidence suggests a general phenomenon whereby successful cities with well-established centers attract people to work, study, visit and live; the total population and population density both increase; the authorities recognize that the road network cannot be expanded to accommodate more car use without damaging the urban environment; hence decisions are made to invest in public transport, particularly rail, which provides speedy and reliable travel compared with cars, buses and taxis on congested roads, as well as to improve facilities for walking and cycling. A common characteristic is the existence of a historic city center that people find attractive for work and leisure, where declining car use increases the attraction. In the absence of an appealing downtown district, population growth may lead to continued low-density development, with no mode shift away from car use.

In the 20th century, increasing prosperity was associated with increasing car ownership and use in developed economies. In the 21st century, increasing prosperity is associated with *decreasing* car use in big cities having attractive centers, growing populations and that can afford to invest in an extensive network of high-quality public transport as an alternative to the car on congested roads. A question for low income economies, where car ownership is still relatively low, is whether the peaking of car use in large, densely populated cities use can be avoided, transitioning instead to the modest mode share envisaged in the developed economy cities discussed above [10624].

Impact of Technology

Innovative technologies have been central to the historic development of transport. Until the coming of the railway, travel generally was at walking pace, with few able to take advantage of horse-drawn vehicles, which were not much faster on poor roads. Time has

always been a constraint on the distance that could be traveled. In the 19th century, the railway harnessed the energy of coal to achieve higher speeds and mass mobility that transformed economic and social geography. In the 20th century, the motor car using oil, the other fossil fuel, allowed speedy door-to-door travel, with further gains in access to desired destinations, opportunities and choices, within the time constraint of about an hour a day average travel time. The cessation of growth of average distance traveled by car in part reflects the inability to travel both faster and more safely on uncongested roads, and the difficulty of mitigating road traffic congestion.

There are new technologies, both deployed and entering the market, that will change how cars are propelled and used. Electric propulsion in place of the internal combustion engine will eliminate tailpipe emissions of carbon dioxide and noxious pollutants, but will not change the basic features of the car. Automated vehicles will reduce, or even eliminate, the role of the driver, but are unlikely to permit faster travel on existing road systems. Digital navigation devices are used widely, offering optimal routing through congested networks and estimates of journey time that mitigate the uncertainty associated with road traffic congestion. Digital platforms provide improved ways of locating vehicles for hire and sharing vehicles. All these innovations improve journey quality without having much impact on the speed of travel and are therefore unlike past transport innovations that offered step-changes in velocity (Metz, 2019).

Innovative technologies may affect car use by offering alternatives to travel from home. Online shopping is a likely contributory factor to the downward trend in shopping trips in England—15% decline in numbers of trips and 18% in distance, between 2002 and 2018 (NTS, 2018). Journeys to work in England have also been declining, from 7.1 per worker per week around 1990 to 5.7 in 2014, attributed to people working fewer days a week, more able to work from home, and more self-employment (DfT, 2016). The coronavirus pandemic of 2020 accentuated these trends, as well as demonstrating the scope for interactions made possible by personal travel to be replaced by interactions mediated virtually by digital technologies. On the other hand, digital technologies make possible a wider range of personal contacts, which may prompt a post-pandemic revival of travel to reinforce relationships through face-to-face engagement. The net long-term impact on travel behavior is unclear.

Conclusion

As the developed economies moved from the 20th to the 21st centuries, car use per capita generally ceased to increase, bringing to an end nearly two centuries of growth of personal travel that began with the development of the railways in the first part of the 19th century. The evidence suggests that the main contributory factors to this cessation of growth were saturation of demand for daily travel, reflecting high levels of access achieved; population growth in successful cities where space for car use is limited; and technological limitations that prevent faster travel, given constraints on travel time. Despite the deployment of new transport technologies, car use per capita seems unlikely to change much in the future.

Biography

David Metz is honorary professor in the Centre for Transport Studies, University College London, where his research focuses on how demographic, behavioral and technological factors influence travel demand. After an initial career in biomedical research, he took senior posts in a number of UK government departments, as both policy and scientific advisor, including 5 years as Chief Scientist at the Department of Transport. His recent research has been summarized in a book entitled 'Driving Change: Travel in the Twenty-First Century' (Agenda Publishing, 2019).

Glossary

NMS New Mobility Services linked to the sharing economy and the development of new ways to reach customers (ride-hailing, ride-sharing, car share, bike share, carpooling, micromobility, including e-scooters) using new modes of transport.

MaaS Integration of various forms of transport services into a seamless integrated mobility service accessible on demand and via a single portal, with user-centricity and customers at its heart.

TAG Transport Appraisal Guidelines developed by the UK Department for Transport. TAG provides information on the role of transport modeling and appraisal, and how the transport appraisal process supports the development of investment decisions to support a business case.

DRT Demand Responsive Transport flexible mode of transportation that adapts to the demands of its user groups, often accessible via a digital platform or mobile app.

ABM Agent-based modeling uses a synthetic population of agents to understand complexities in human behavior. Agents are entities with their own behavior, preferences and activities to fulfill. When it comes to model mobility, agents can be either the user of the service (static agent since their plan consist of a sequence of trips or activities) or vehicles (dynamic agents with no prior predefined activities). Activity based Modeling is a specific ABM where agents have activity plans to fulfill.

Synthetic Population Designed to resemble a real-world population with respect to sociodemographic characteristics and spatial information. In agent-based modeling for the transport sector, each agent in the population is associated also with daily activity plans.

Agents Social elements/persons in a model that can interact with each other and an environment, and pass information between each other. Agents might represent animals, individuals, households, organizations, or even entire countries.

Properties Agents have properties. A property might be a memory, a state, a characteristic, or attribute, such as age, gender, income, speed, or health. Properties are discrete, and can be binary (yes/no), or numerical (e.g., on a 1–100 scale).

Environment This is the virtual world in which agents act and interact. It can be 2D, or 3D. A neutral medium with no effect on agents whatsoever, or a prime determinant of their ability to act. It can be abstract and imagined, or a replication of real-world buildings, cities, or vast geographies (road networks extending to few blocks up to cities or regions).

Rules These govern what happens when agents interact (or come into contact) with each other, or their environment. They may also govern how learning and adaptation occur within an environment. These rules may be pre-programmed, or automatically inferred in the case of some smart ABM platforms.

Introduction

According to the United Nations, the population residing in cities is projected to reach 60% by 2030. Changes in travel behavior and car ownership are pivotal to enable a switch to low-carbon transport solutions. Within the transport sector, road transport is considered the biggest emitter (more than 70% of all GHG emissions in 2014). The delivery of seamless, personalized, shared and integrated mobility has the potential to enable the Mobility as a Service (MaaS) vision, however, there is a lack of understanding around the drivers allowing people to share and no best practice is available to assess the performance of the services and their impact/interaction with the public transport.

Autonomy, flexibility, and digitalization are changing the way we travel, however, business models established around on-demand, ride-sharing services have not proven to be successful in the long term. The process of trial and error established to attract demand randomly produced a negative effect on congestion, a decline in patronage on the public transport, with whom mobility services seek a spontaneous integration. The process to launch and maintain these services is missing some fundamental understanding on travel behaviors and customers' mobility needs, not currently captured in the market research carried out ahead of the launch. Perceived bias and habits should be considered in a comprehensive analysis that takes in consideration current travel patterns.

Local and transport authorities currently are unable to assess the impact that New Mobility Services (NMS), Demand Responsive Transport and Mobility as a Service (MaaS) might have on travel behaviors and any unintended consequences that might derive from the introduction of these on-demand mobility services.

Transport models currently in use to assess the demand for travel are unable to consider the full complexity of travelers' needs and the contribution shared mobility makes in a public transport system, both in urban and rural environments.

The increased complexity of travel demand models to fit modern lifestyle, and the demand for flexibility led to travel patterns being more difficult to predict, as well as a reduced availability of private transport for certain population groups with a subsequent increase in social exclusion. New methodologies are emerging to take into account the end-to-end users' journey, multimodality and the ability to represent shared mobility and autonomous flexible services. Moreover, the role of big data and new data sources, such as location-based data (i.e., mobile network data and global positioning systems data), integrated with data fusion processes and machine learning, have increased the spatial and temporal granularity of next generation demand models.

This article presents an evidence base of current market needs, current industry capabilities and defines the problem space in the implementation of NMS and the adoption of MaaS schemes.

Literature Review

In the transport modeling sector there are currently no robust tools and techniques, covered by guidance, to allow a commissioner of transport services, such as a local authority, to assess the investment case for introducing NMS or MaaS. New business models to support mobility services within the transport sector are flourishing around Europe and the rest of the world, however, identifying the most suitable locations for their introduction, and potential demand for the services, is more often a process of trial and error, as none of the key modeling software packages have the capability to fully predict demand for these services and assess the impacts of their introduction on the more complex and less flexible Public Transport ecosystem. New services are, therefore, often viewed as negatively disruptive, especially if not designed to complement existing public transport services or promote more sustainable active modes (walking and cycling), as well as being deployed in a potentially inefficient way.

NMS have great potential to provide greater flexibility for travelers and deliver better connectivity between modes, which have historically been designed and operated within respective silos. If they are designed around the needs of the customer and integrated appropriately with existing transport offerings, these services can provide new cost-effective, on-demand solutions and be used to manage demand on congested networks by incentivising alternatives, helping to maximize the capacity and resilience of existing infrastructure.

Due to the emerging nature of these NMS, transport operators and local authorities also have no corresponding guidance for the process new service providers must go through to demonstrate the likely impacts on network operations in order to receive licenses to operate. Current standards and guidelines for scheme assessment through modeling (such as those presented in the UK Department for Transport's TAG) are based around assessing and appraising investments in infrastructure and provide a limited opportunity for industry to evolve to consider investments in NMS as viable alternatives.

The Era of MaaS

Transport modeling has been traditionally facing significant challenges to realistically represent mobility. Many uncertainties, mainly but not only related to human behavior, have hindered the development of robust models, able to holistically capture the diverse dynamics of transport networks. In an emerging transportation future, where NMS and MaaS concepts will be widespread, users are likely to perceive traveling substantially differently. Although the term MaaS has been extensively used over the last few years, no formal definition has yet been agreed. This could be partly explained by the fact that MaaS is a relatively new concept which has not yet fully developed. Most definitions suggested by various entities revolve around principles such as integration, user-centricity and personalization. [Mulley \(2017\)](#) focuses on the disutility nature of traveling and states that "The concept of MaaS recognizes the way in which travel is typically a disutility for the traveler who is motivated only by consuming at the destination." Transport Systems Catapult definition highlights the range of available choices to the traveler, defining MaaS as a "new concept that

offers consumers access to a range of vehicle types and journey experiences" (Datson, 2016). Mars and Arup (Falconer et al., 2018) highlight the dual nature of MaaS distinguishing two inherent elements, namely the "physical transport provision" and the "medium for accessing the service". MaaS Alliance, a public-private partnership aiming to create a common foundation approach towards MaaS, defines it as "the integration of various forms of transport services into a single mobility service accessible on demand". Atkins et al. (2015) propose a broader but more comprehensive definition: MaaS is "The provision of transport as a flexible, personalized on-demand service that integrates all types of mobility opportunities and presents them to the user in a completely integrated manner to enable them to get from A to B as easily as possible".

Changing Travel Behaviors

According to recent studies, travel behavior is gradually getting more difficult to predict (Department for Transport, 2018; Ferreira et al., 2007; Holmberg et al., 2016). Various reasons have contributed to this, including the modern lifestyle, the increased demand for autonomy and flexibility, the diverse travel patterns, as well as, the reduced availability of private transport for certain population groups.

Another factor affecting travel behavior stems from the digitalization of the transport system, which allow travelers to make better decisions regarding their journeys. Due to the availability of accurate and timely information, travelers now can optimize their journeys and adjust their travel patterns accordingly, often leading to unexpected travel behavior.

In addition, the imminent technological advances (e.g., autonomous and connected vehicles and unmanned aerial vehicles) are very likely to radically change the rules of mobility. For instance, the flexibility and ease of use of autonomous vehicles could unlock new segments of travel demand which are currently suppressed, such as the elderly population and those who are mobility impaired (Harper et al., 2016). This increased demand could put current transport networks at, or over, their available capacity and therefore leave them unable to cope.

In light of the potential for travel behavior to change significantly, a thorough assessment of the effect that the widespread introduction of NMS would have on the transport system, requires advanced modeling techniques which are not readily available (Ben-Akiva et al., 2007; Jittrapirom et al., 2017). Moreover, Intelligent Transport Systems (ITS) have become an essential component of transport networks and many studies have examined its impact (Dia, 2002; Chorus et al., 2006), and its ongoing role which is generally neglected in most of the currently available transport models.

Traditional transport models (e.g., four-step modeling) face difficulties in realistically representing the complex dynamics of the emerging transport environment (Jain, 2016; Mladenovic and Trifunovic, 2014; Rodier et al., 2003). The methodologies applied in these models were developed under a different transport environment, but many of the underlying assumptions may not hold true in the era of NMS.

A four-stage model approach is unable to represent the shared element: the traditional division between highway assignment and public transport modeling does not allow the model to represent the interaction between private on-demand shared services and fixed scheduled public transport service (Franco et al., 2020a). The second main barrier in using strategic modeling tools at macroscopic level is represented by the aggregated trip-based approach adopted. A deep knowledge on how users travel over a day and what is their travel patterns is required. This is necessary in order to provide a valid alternative to private owned cars and implementing the integration of mobility services envisaged by MaaS. For example in Franco et al. (2018), the analysis of highly granular disaggregated Mobile Network Data (MND) demonstrated that a higher number of trips in an area is not providing a necessary condition that indicates an area with potential customers for a mobility service. Hence, the only viable solutions to model NMS would be the adoption of activity-based modeling approach which can derive either simple or complex travel patterns for users.

In many cases though, certain simplifications can enable NMS to be simulated by conventional methodologies (e.g., park-and-ride, regular taxis, fixed route transit). As a result, existing transport demand modeling software can be reconfigured in order to address NMS in a conventional way, but these approaches cannot always model NMS in the level of detail that is required for the operators and the Local Authorities seeking for a balanced integration between NMS and public transport services.

Modeling to Assess the Impact of MaaS and NMS

The first step toward the development of robust demand modeling tools and methodologies requires an in-depth understanding of NMS nature, as well as the challenges hindering their introduction, as shown in Fig. 1. Transport models can contribute to assess different implementation strategies for MaaS with their ability to provide a virtual testbed for scenario testing and the possibility to run sensitivity analysis. This can help to identify and frame uncertainties before embarking into NMS trials. Moreover, transport models can help to get a better understanding of potential problems caused by the introduction of NMS and their subsequent effects on multiple levels (e.g. land use, jobs, growth, congestion, public transport).

Transport modeling could also be used to identify scenarios where reduction of patronage from public transport sector is likely and assess mitigation strategies. It could be used to quantify accessibility improvements for areas covered by NMS and facilitate the estimation of induced demand due to such improvements. From a commercial point of view, proper use of specialized modeling tools could minimize the risk of failure for NMS by assessing their potential prior to their actual roll-out.

However, it is important to define the problem to solve and identify the customer for the model, choosing the appropriate tool and datasets according to their needs and the stakeholders involved in the creation of the model. When mobility services and

Figure 1 Challenges in implementing New Mobility Services and Mobility as a Service.

mobility on demand are introduced key questions that a model should be able to address look quite different depending on each stakeholders' perspective.

During the "Business Case for New Mobility Services (NMS): Demand Modeling Tools" project (CPC, 2019), a series of stakeholder engagement activities were undertaken with the aim to define the problem space, evaluate the market needs and the existing modeling landscape capabilities.

Stakeholders Perspective

Each stakeholder has different views on what MaaS is and what should deliver. Transport modeling and specifically demand modeling is identified as a way to de-risk the introduction of NMS and turn them in a sustainable viable proposition to link up traditionally less flexible public transport services.

Personal preference, accessibility, and attitude toward shared mobility play a big role in understanding demand. Estimating the effect NMS have on travel choices both on a short-term basis (e.g. planning and operational purposes) as well as on a long-term basis (e.g. development purposes) can be a challenge. Moreover, NMS should be inclusive, increase access to transport and minimize transport poverty, defined as lack of access to transport services. NMS are not expected to be used for long journeys but only to cover those first/last mile journeys during commuting to work.

Integration at multiple levels with the more complex public transport ecosystem should be introduced to allow users to access MaaS through a single application which provides access to mobility, with a single payment channel. However, there are no adequate tool to predict demand for NMS, hence hindering the implementation of sustainable MaaS schemes around the world.

Local Authorities' Perspective

When mobility services and mobility on demand are introduced, key questions that a model should be able to address are different depending on each stakeholders' perspective. From a transport/local authority's point of view the most interesting questions are focusing on the wider social, economic, and environmental benefits (or disbenefits) that the introduction of NMS could entail as shown in Fig. 2.

Local authorities see NMS as a way to increase the integration of mobility services, to enhance the actual provision of public transport services, and sometimes substitute it in areas where the level of service is too low to justify a continuous PT service running. They would like to introduce innovations to optimize public transport services, however they do not know how to implement the appropriate combination of mobility services to implement MaaS.

The ability to provide a virtual testbed for scenario testing and the possibility to run sensitivity analysis can help to identify and frame uncertainties before embarking into NMS trials. Transport models can help to get a better understanding of potential problems caused by the introduction of NMS and their subsequent effects on multiple levels (e.g., land use, jobs, growth, congestion, public transport).

Transport modeling could also be used to identify scenarios where monopolization of the existing transport market could occur and assess mitigation strategies. It could be used to quantify accessibility improvements for areas covered by NMS and facilitate the estimation of induced demand due to such improvements.

Figure 2 Key areas of concern from a Transport or Local authority's point of view regarding NMS and MaaS.

Transport Operators' Perspective

Transport operators are mostly interested in transport models which will enable them to prepare for a successful and smooth introduction of mobility services, minimizing the risk of failure for NMS by assessing their potential prior to their actual roll-out. Some key areas of concern from a transport operator's perspective regarding the introduction of NMS and MaaS are related to revenue, costs and operations of the service.

These key areas could be informed by the application of specialized transport modeling tools. Such tools can enable for instance, the design of an appropriate pricing structure as well as the estimation of the required infrastructure investments (e.g. required fleet size and personnel). Moreover, sensitivity analysis and simulations can be used to assess the cost of multiple implementation strategies without the need of expensive trials. Finally, a relevant transport model can provide insight regarding the identification of appropriate target groups for the service and the locations where to run it.

Another area of great importance to transport operators is related to the day-to-day operations and how these could be optimized in order to provide a better service for the customer while minimizing costs, such as optimum routing and efficient allocation of the service to the identification of the most appropriate area of coverage. A special mention was made regarding the importance of modeling tools (especially simulation-based ones) to help with the mitigation of disruption and unexpected events. Operators and transport providers are keen on identifying ways to deal with disruptive events while at the same time maintaining an acceptable level of service.

Data Required to Model MaaS and NMS

Transport models do not differ from other models in terms of data requirements since they also depend on a wide range of information to make accurate predictions. Although significant improvements have taken place over the last decades regarding data availability, many general concerns around the usability of data are hindering the use of data-driven approaches to transport modeling. These data requirements are grouped and presented in Fig. 3.

A better use and enhancement of already available sources (e.g., census, travel surveys, traffic counts) which have reliably assisted transport modelers for many years should be promoted, and therefore efforts should be concentrated towards their improvement (e.g., acceleration of their update, greater granularity). For instance, census data usually include most of the required information for most transport models, but their 10-year update cycle can quickly render them obsolete.

The recent technological advances, especially in the field of telecommunications and personal connectivity (e.g., smartphones, Internet of Things, Location-based data such as Mobile Phone data and GPS) has enabled the acquisition of very fine-grained data in vast quantities. The issue with using them for transport modeling purposes usually derives from the lack of standards to anonymise data. Data providers and transport modelers should cooperate in creating methodologies that will enable the use of data at a highly disaggregated level without any compromise on the protection of personal information. As an example, Mobile Network Providers have at their disposal detailed information regarding the mobility patterns of their customers. These data can be used to inform a transport model (Franco et al., 2020), but no widely accepted methodology as to how this information can be securely anonymised and aggregated without losing information at disaggregate level has been presented so far.

Figure 3 Identified data requirements.

Generally, a data-driven approach to transport planning is perceived as more secure and fit to model new trends and technologies, however, since mobile network data is used and collected for other industries, data mining and fusion is fundamental to provide a good data input for transport models. Especially for modeling the impact of MaaS, an activity-based approach would be preferable to represent the end-to-end user journey because provides the possibility to represent real-world and complex travel patterns when built using highly disaggregated data.

Demand Modeling—Key Changes

Modeling demand for mobility services is substantially different from the traditional approach due to the introduction of the “user centricity” element. The provision of a fully inclusive mobility service to satisfy all users’ needs, relies on the ability to model the end-to-end users’ journeys and the interdependence existing between one trip and another. This requires a better understanding of travel behavior and their attitude to share, so the likely uptake of new trends in the mobility sector can be derived.

Modeling tools have been experimenting more on Mobility on Demand and Demand Responsive Transport (DRT) with a specific focus on fleet operations and management without considering demand modeling as an integral part of the business model.

There are few elements that need to be considered when it comes to modeling MaaS:

- The ability to represent NMS’ integration with existing public transport systems;
- The ability to consider door-to-door, multimodal journeys and the correlation between each trip;
- The shared element of on-demand mobility services;
- The ability to provide an overview of the demand for travel over 24 h to serve current users but also capture latent demand in different time of the day and for a large-scale area.

Based on these characteristics, Transport Agent-based Models (ABM) are becoming a viable alternative solution to the traditional trip-based approach. A specific characteristic of this type of model is that they require a higher granularity data and are computationally intensive. All features that can be addressed with the data rich environment created in smart cities and cloud computing.

Connected Places Catapult has already explored this solution in the two Innovate UK funded projects “Mobility on Demand Laboratory Environments” (MODLE) (Franco et al., 2018, 2020a) and Merge Greenwich (Segui-Gasco et al., 2019), where ABMs are using a data-driven approach to test flexible Demand Responsive Transit, operated either with traditional or automated vehicles. ABMs can be developed either using a trip-based approach or an activity-based approach. In the latter case, the activity-based approach allows to model the complex interaction between flexible private mobility services and the more complex public transport ecosystem. In the MODLE simulation, demand and travel behaviors were informed by anonymised and aggregated Mobile Phone Network Data (MND). MND reveal real travel patterns from users using trip-chains data to derive an activity-based approach to model complex travel patterns for the daily activity plans of the synthetic population. Results showed that the traditional datasets based on the use of disconnected trips produce a heavy congested network which does not provide useful insights in the behaviors of users (Franco et al., 2020).

The requirements identified for creating demand models to represent and appraise NMS are reported in Table 1.

Table 1 Requirements for demand models to model mobility (Franco et al., 2020c).

Requirements to create a large-scale demonstrator for modelling and appraising New Mobility Services'	
Model	• Agent Based Model with Activity based approach: • End-to-end users' journeys • Multimodality • Contribution of shared Mobility towards increase in patronage in Public Transport • Microlevel approach to include new technologies, such as CAVs, for shared mobility services running with autonomous and conventional vehicles using dynamic agents • Appraise impact on the network and the environment
Data landscape	• Location based data (Mobile Network Data, GPS, satellite data, ...) as data input to generate daily travel patterns from users • Use of highly disaggregated data to make use of big data source coming from sensors and new technologies • Use of existing Data Centres, with consistent and long records of events for calibration and validation purpose of the model • Appraise the Impact of New Mobility Service on the environment using a highly granular environmental data
Other factors to consider for shared mobility	• Attitudes of people towards sharing to understand the uptake of New Mobility Services and how the Mobility as a Service offering will be affected by this propensity • Changes in the value of time for ride-sharing mobility services and how this will affect the costs in the model • Understanding the willingness to pay when users are presented with a range of conventional and new transport options • The use of Artificial Intelligence to accelerate the procedure to automate the travel pattern recognition • Integration with legacy models for strategic modelling and optimization of the mobility service operations

Based on the requirements mentioned in [Table 1](#), a new methodology was created during the 2019 "Demand Modeling and Assessment through a Network Demonstrator" (DeMAND) project, which allows to generate a large-scale agent-based model, which represents a regional digital twin ([Franco et al., 2020b](#)).

The DeMAND agent-based model has demonstrated the ability to model a large-scale area, using only readily available network information and latest generation of Mobile Network Data providing a tool to inform the transport authorities in the introduction of shared mobility. The use of agent-based modeling and the behavioral models enhance the public transport services through a bottom-up approach that holistically consider all transport choices available to users and their preference for travel, but also the different values of time associated with each mode of transport (i.e. active travel, public transport, shared mobility, private car). The methodology can also be extended in newly developed areas, where little information is available and in rural areas, which are typically considered of low demand for travel.

Conclusions

To implement MaaS and NMS, a full understanding of travel behaviors and transport choices is pivotal to assess the impacts on congestion, the environment and health of population. The public transport sector was adversely affected by the introduction of NMS and as such transport models could help in identifying impact, gaps, lack of service provision and integration of systems at various level. However, the potential of this methodology for demand modeling can stretch further given that the agent-based model with activity-based approach can offer the opportunity to test various policy interventions. For example changing the demand for travel, such as the restrictions introduced during the Covid-19 pandemic, either during the lock down phase or during the reopening of the activities, the possibility to target specific segments of the population or restricting certain activities.

Traditional traffic modeling software platforms are not designed to allow for the introduction of new modes of transport or to measure the impact on people's activities following the introduction new policy interventions, especially at large-scale, as they focus on aggregated trip-based, siloed mode-based approaches, whereas the focus in this new domain needs to consider people-centric,

multi-modal, end-to-end journeys, as well as grouping individuals according to their socio-demographic characteristics and even personal preferences during traveling.

Transport is expected to face multiple challenges and therefore tools able to provide insight regarding its future are essential. The tools currently available to transport operators and authorities, are not adequate to answer the complex questions related to mobility and will most likely require significant enhancements or complete re-engineering. Even though the need for development of more sophisticated transport models has already been recognized (Department for Transport, 2018; European Commission, 2016), there seems to be a long way until transport models will be capable to accurately represent travel behavior in the era of NMS and MaaS.

The Connected Places Catapult has started to develop tools and methodologies capable of providing answers. The data preparation approach and open source modeling tools trialed during the DeMAND project offer promising advanced capabilities in this field over commercial tools, however agent-based models do not yet offer a stable, de-risked platform from which the modeling industry can take over. Agent-based Models are subject to calibration and validation issues due to lack of guidance and standardization. Further investment in this research and convening the knowledge of industry and academia will help to stimulate the development path of modeling tools and techniques as well as leading the ability to create demonstrator models capable of modeling the impact of NMS at scale.

Acknowledgment

The author would like to thank the UK Department for Transport for funding the “Business Case for New Mobility Service: Demand Modelling tools” to advance the knowledge on large-scale demand agent-based modelling for urban and rural mobility solutions; and Nila Sari from the Department for Transport for the constructive feed back, Dr. Djibril Kaba and Dr. Haris Ballis, and other colleagues at the Connected Places Catapult for their support during the development of the project.

Biography

Patrizia Franco is a Principal Technologist in Demand Modelling at Connected Places Catapult (created in 2019 and formerly known as Transport Systems Catapult and Future Cities Catapult) interested in research and innovation in new and emerging mobility services.

Former researcher in Transport Modelling and Data Analysis at Newcastle University (UK), she has more than 15 years' experience in transport planning and policy, strategic transport models, public transport systems and is specialised in Agent-based and Activity-based Modelling to model MaaS and Demand Responsive Transit to achieve greater sustainability and resilience in smart cities.

Patrizia is currently technical lead for collaborative projects working with the UK Department for Transport on urban and rural mobility issues, such as “Assessing Sustainable Transport Solutions (AsSeTS) for Rural mobility” and DeMAND (Demand Modelling and Assessment through a Network Demonstrator) to improve the knowledge base around data-driven demand modelling tools and de-risk the uptake of NMS in Urban and Rural Mobility.

The Surge of Interest in Walkability

There is a global trend to advocate for walking and more pedestrian-friendly places (European Commission, 2013; UN-Habitat, 2014; WHO, 2018). This widespread policy agenda can be attributed to decades of multidisciplinary research and planning exercises showing the positive impacts of more walkable places and people walking (Berg et al., 2017; Mackenbach et al., 2014). To illustrate these findings, the report "Cities alive: Towards a Walking World" (ARUP, 2016) lists 50 benefits categorized in social, economic, environmental, and political sectors (Fig. 1).

Pedestrians travel on foot to reach specific destinations, engage in cultural and socio-economic activities, walk and use public spaces for physical or restorative exercises, with the possibility of combining different purposes in the same walk. The positive impacts, together with the ubiquity of walking and the disparity of their purpose, have drawn the attention of a wide variety of policy makers who increasingly see walkability as a key factor to address current challenges in the areas of public health, urban and transport planning, economic and social development, environmental sustainability, and cultural enrichment. This surge of interest came after a steady decline in walking activity in western societies in the 1970s, mainly attributed to suburban sprawl and the creation of car-oriented urban landscapes. Such developments along with an increasing sedentary lifestyle and diet changes, were directly related to new crisis, such as the obesity pandemic, traffic-related high mortality, lack of social cohesion, and environmental deterioration (Marshall et al., 2009). In the search for solutions, researchers, practitioners, and advocates focused on the alleged benefits of walkable places and active walking communities.

The development of walkability research was heavily influenced by the particularities of different disciplines that initially addressed this topic. Transport professionals initially focused on large-scale determinants, such as the urban fabric, land use and transport networks, to study pedestrian accessibility and connectivity to destinations and services (Cervero and Kockelman, 1997). Meanwhile, urban planners focused on the streetscape and pedestrian activity in public spaces (Gehl, 1987), where the street is redefined as an arena for social interaction and not just a means of access (Appleyard, 1981). Health scientists, on the other hand started to address the obesity pandemic at the end of the 20th century with new studies concluding that moderate physical activity constitutes a key determinant on health (Hardman and Stensel, 2009) and subsequently identifying walking as the most accessible and affordable source of health-enhancing physical activity (Owen et al., 2004). The subsequent adoption of transport methods and planning principles by health scientists prompted a new multidisciplinary approach (Frank et al., 2005).

The surge of empirical studies proving health benefits made walkability a political priority. This encouraged different disciplines to use this new measurable concept to investigate further implications of pedestrian activities and pedestrian-friendly environments. Economists focused on the associations between walkability and property value, store sales, and cost savings related to public health, transport and energy consumption (Litman, 2018). Sociologists addressed the relationships between walkability and social cohesion, interaction, public participation, and social justice (Anciaes, 2011). Furthermore, geographers and behavioral scientists

Positive impacts of walkable places and pedestrian communities

SOCIAL BENEFITS		ENVIRONMENTAL BENEFITS	
Health and wellbeing		Virtuous cycles	
Promoting active lifestyles Addressing the obesity crisis Reduction of chronic disease Improving mental health		Decreasing dependency on non-renewable resources Optimising land use Addressing air pollution Reducing ambient noise Improving urban microclimate Increasing permeable surface for water drainage

Figure 1 Benefits of walkability (ARUP, 2016).

attempted to define an overall common ground for walkability research where all the relevant elements are integrated and interconnected in proposed frameworks (Andrews et al., 2012). Whilst initially policy making addressed walkability by focusing on isolated and specific issues, such exercise to tackle obesity or minimizing pedestrian injuries in case of collisions, it gradually combined policy objectives and measures to address more multidisciplinary issues, such as sustainable urban mobility and liveability. The COVID-19 pandemic has further accentuated the importance of walkability as a policy to increase walking and reduce infection risks in crowded public transport.

Walkability Policy Objectives

Policies aiming at enabling and promoting pedestrian-friendly places and pro-active pedestrian communities are broad in scale and range. This section presents international policies developed to support and enable pedestrian mobility and other activities. Although the majority of these policies have no legally binding force for individual states, they constitute a guide for policy making and legal reform at national and local scale.

Policies to Ensure Pedestrians' Rights

The 1988 European Charter of Pedestrians' Rights constitutes the first attempt to establish a framework to integrate a pedestrian-friendly approach into policies and practices. This document elaborates upon a list of pedestrian rights and concepts. First, the need for healthy and safe pedestrian environments. Second, the need for pedestrian accessibility to destinations based on walking distance and pedestrian accessibility at street level, including physically and mentally impaired pedestrians with limited mobility. Third, the need to preserve public space for socio-cultural interactions. Fourth, the need to balance or reverse the car-oriented infrastructure, giving back public space to pedestrians and limiting the negative impacts of excessive car use. And finally, the need for an integrated multimodal transport system, with significant importance to public transport, to aid pedestrians when walking becomes unfeasible.

In a more recent context, the 2006 International Charter for Walking (Walk21) was recognized by the World Health Organization (WHO) as a comprehensive framework to help authorities refocus existing policies and create a culture where people choose to walk.

Policies to Assure Pedestrian Accessibility

While mobility is an integral part of life, accessibility is necessary to participate in society and can be seen as a prerequisite for obtaining income and wealth. The 2017 European Pillars of Social Rights includes the right to equal opportunities and access to the labor market, education and to goods and services available to the public. Based on this concept, transport systems should offer accessibility to destinations regardless of the means of transport. In this case, pedestrian accessibility to destinations is based on proximity and availability of goods and services within walking distance, which can be assessed at urban scale.

A second perspective for pedestrian accessibility is based on the need for universal design of the built environment to be usable by all people, regardless of their physical or mental capabilities. This type of accessibility is usually assessed at street level and can be guided by the principles of the 2006 United Nations Convention on the Rights of Person with Disabilities. Although such provisions are promoted across financial instruments such as the European Structural Funds, there is currently no obligation at EU level to meet accessibility criteria for new or renovated infrastructures. The third perspective on pedestrian accessibility is based on the availability of public space dedicated to pedestrians to engage in cultural and socio-economic activities, which can be assessed through the study of urban land use distribution. Based on principles of equity and social justice, the main concern in this respect is the large amount of public space that is often dedicated to the movement and parking of cars at the expense of pedestrians (see for example [European Commission, 2004](#)).

Policies to Provide Pedestrian Safety and Security

The main concern on pedestrian safety is related to collisions with motor vehicles. At least 51,300 pedestrians were killed on EU roads over the period 2010–18. While the number of pedestrian deaths has decreased by 2.6% on average each year in the EU over the period 2010–18, this trend is inferior to the annual reduction of motorized road user deaths over the same period (3.1%) (ETSC, 2020).

Since 2003, legislation has been introduced at EU level to reduce pedestrian injury risks from traffic. These measures are limited to crash-friendly car fronts, advanced braking systems or blind-spot mirrors, which are technical requirements where the EU has legal competence over Member States. However, the EU has no legal binding force on other important actions, such as speed management, adequate infrastructure for nonmotorized transport and separation of dangerous mixed traffic. Since these issues are mainly related to urban management, most of the actions have to be in accordance with the Commission's 2009 Action Plan on Urban Mobility, which can only be incorporated into the legal framework by national and local authorities (see also next section).

One concept that is dictating the current policy on transport safety with relevant implications to pedestrians is the Vision Zero approach, conceived by the Swedish Government and Swedish Industry in 1994. It has since influenced policies, materializing in the EU road safety policy framework for 2021–2030 "Next steps toward Vision Zero". It specifically recognizes the responsibility for road

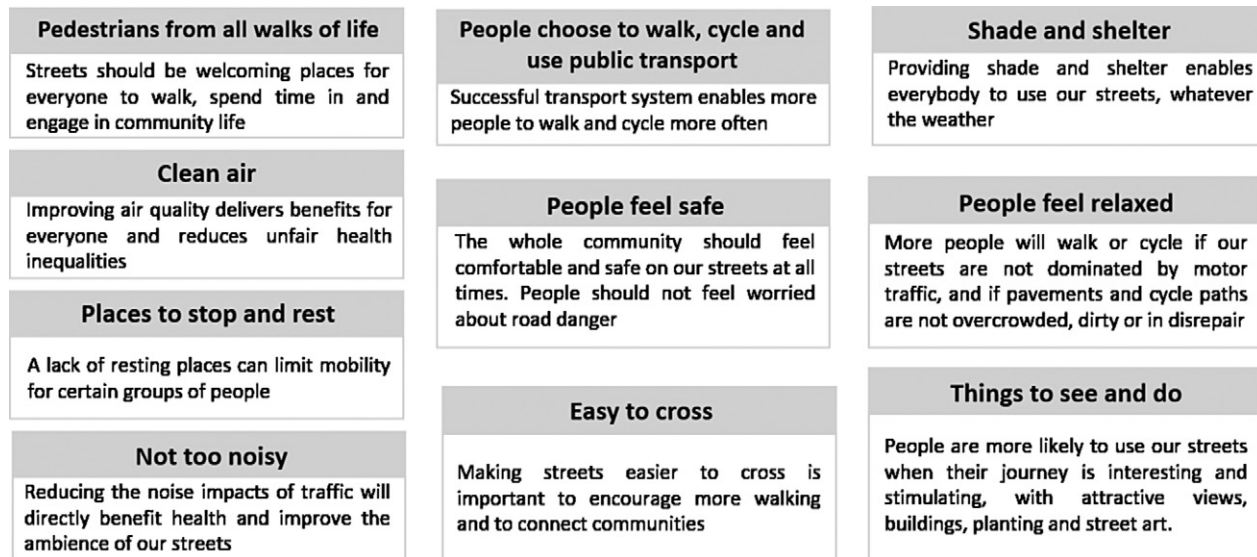

Figure 2 The 10 healthy streets indicators (Transport for London, 2017).

traffic safety as being shared between system designers and road users. One of its key principles is a 30 km/h speed limit based on the physical tolerance for a pedestrian to be hit by a well-designed car.

Although the main risk for pedestrian safety remains primarily linked to conflicts with traffic, there are growing concerns related to various forms of crime and terrorism across a number of cities worldwide further limiting pedestrian safety and security.

Policies to Promote Walking as a Health-Enhancing Activity

There is extensive literature on the physical and mental health benefits of walking as a moderate exercise and recreational activity, as well as the positive impacts of pedestrian-friendly environments to public wellbeing (Kelly et al., 2017). The WHO recommends adults to do at least 150 min of moderate-intensity aerobic physical activity throughout the week, performed in at least 10 min duration, which can be easily achieved by walking. Thus commuting on foot is increasingly integrated as an important contributor to transport-related health strategies (WHO, 2018).

At city level, London started to develop pedestrian strategies in the late 90s and published the first Walking Plan in 2004 addressing the environmental, socio-economic and health benefits of a more walkable city. Further on, the 2014 Transport Action Plan constituted a noteworthy example of transport and public health policy. This plan takes a “whole street approach” based on 10 Healthy Street Indicators (Fig. 2) to make streets more inviting for walking and cycling (Transport for London, 2017). The 2018 Walking Action Plan further elaborates on this Healthy Streets approach and envisions a future walkable city with specific and ambitious targets. It proposes four main actions: building and managing streets for people, planning and designing for walking, integrating walking with public transport, and leading a culture of change. It also consolidates the political willingness to achieve them with the appointment of the first ever walking and cycling commissioner.

Policies to Encourage a Modal Shift

The introduction of the mass-produced car in the 20th century represented a revolution in mobility and a milestone in the democratization of movement. The strive for speed and individual freedom based on car ownership led to a dominant car-oriented development where cities were planned to cater for the needs of private cars to the detriment of any other means of transport, and colonized most of the public space previously reserved for pedestrians. However, car-dependent cities started to experience a deterioration in the wellbeing of urban population as a result of traffic congestion, pollution, and road accidents.

The 2010 European Transport Policy White Paper aimed at reducing private car use while promoting more sustainable mobility at national scale. At the same time and considering the rapid urbanization across Europe, transport policies turned their attention to urban areas with the publication of the 2007 Green Paper: Towards a new culture for urban mobility. The need for rethinking urban mobility led the EU to develop a series of proposals and formulate collective policies to be implemented locally with the overall aim of promoting an urban mobility that allows for economic development, while preserving the quality of life of inhabitants and the protection of the environment.

One of the main proposals was to optimize a multimodal transport system, organizing comodality between public transport and individual modes of transport, and encouraging active travel. At this stage, European urban mobility was closely linked to environmental protection, healthy environment, land use planning, housing, and social aspects of accessibility and mobility. Thanks to this urban scale approach, walking has since been included as a relevant means of transport in European policies. The

2011 White Paper indeed considers walking as a relevant contributor to clean urban transport and commuting. The concept of Sustainable Urban Mobility Plans (SUMP) provides for a paradigm shift by focusing on people rather than directly on transport, with the aim of creating the much needed shift to greener alternatives to car ownership and use (European Commission, 2013).

This transport planning shift was reinforced further after the publication of the United Nations Sustainable Development Goals, with one particularly addressing sustainable cities and communities. All these current policy strategies set an encouraging scenario for the inclusion and development of walkability in the coming years.

Walkability Policy Instruments

The walkable environment, understood as the combination of the built, natural and social environment, is considered one of the main determinants influencing walking behavior. However, socio-economic status and personal abilities, as well as different purposes of walking, may require different types of walkable environments. Furthermore, it is recognized that the amount and frequency of walking is also influenced by personal mental states and the way in which individuals perceive the environment, as well as the individual's attitudes, norms and other behavioral controls.

In view of the disparity of walking determinants, numerous walkability socio-ecological models interlink all the conceptual factors that may explain walking behavior (Moudon and Lee, 2003). The need for organizing multiple factors and study their relative importance led Alfonzo (2005) to develop the hierarchy of "walking needs", proposing that in order for a person to choose to walk, the main determinants are feasibility, accessibility, safety, comfort and pleasantness. This approach serves as a framework to study how environmental characteristics are perceived to contribute toward experiences that affect people's decision to walk. Similarly, other researchers identified different pedestrian needs, such as usefulness, enjoyment, equity or sense of belonging (Mehta, 2008). All these pedestrian needs can be grouped in three categories. First, feasibility refers to the actual possibility for the walk to be achieved and it is strongly linked to personal capabilities and circumstances, such as physical and mental condition, economic resources and time availability. A second group includes accessibility, connectivity, linkage with other modes and usefulness, which refer to the proximity and variety of certain destinations within walking distance. Finally, there is a range of rather subjective concepts linked to pedestrian safety, comfort, pleasantness and sense of belonging that affect the walking experience. Figure 3 presents a conceptual framework on walking determinants.

In order to enable and promote walking and other pedestrian activities, its interdisciplinary and multiscale nature requires the collaboration of a wide range of experts, agencies and institutions to develop comprehensive programs and policies to combine certain measures and interventions. Although initial pedestrian programs were primarily focused on improving the walkable

Figure 3 Determinants of pedestrian experience and behavior.

Table 1 The '6-Es' for walkability policy

Engineering	Conduct environmental and urban planning to make physical improvements in land use, urban fabric, streetscape, and pedestrian infrastructure toward a more pedestrian-friendly environment. Implement transport planning to provide a multimodal transport system that support pedestrian mobility with affordable and efficient public transport.
Education	Organize awareness campaigns and educational programs on the positive impacts of pedestrian-friendly places and proactive pedestrian communities. Campaigns on the negative impacts of car-dependency, physical inactivity and social isolation.
Encouragement	Implement behavioral change methods to promote walking over private car use, including incentives to pedestrians and disincentives for private car use. Organize events and activities to promote walking. Promote partnerships between governmental institutions with civil, environmental and cultural organizations to organize pedestrian related activities, such as walking to school, car-free events in public open spaces, and competitions amongst walkable cities.
Enforcement	Enforce the laws to prevent unsafe and illegal behavior by drivers and pedestrians to obey traffic laws and respect shared public space or the one allocated to each other.
Equity	Conduct urban and transport planning that takes into consideration all people, regardless of their physical or mental capabilities. Promote walkable places that give children and the elderly independence of movement in urban areas.
Evaluation	Assess the impact and success of the approach. Evaluate if the program or initiative results in an increase of the frequency, quantity and quality of walking and other pedestrian activities. Identify unintended consequences or opportunities to improve the effectiveness of the approach.

environment, as the walkability concept developed, more comprehensive interventions started to appear. The '4-E' approach (Sisiopiku and Cruzado, 2002) combines engineering, education, enforcement, and encouragement concepts. This approach has since been widely accepted by government bodies and advocacy groups in addressing safety concerns and planning for transport systems in general and pedestrian mobility in particular. The program was then upgraded to the "6-E" including the concepts of equity and evaluation (Buttazzoni et al., 2018). Table 1 shows how this approach can be applied to walkability policy.

Engineering: Urban and Transport Planning for Walkability

Walkability policies tend to define an appropriate environment and attempt to make the necessary interventions to provide a more walkable and pedestrian-friendly place. However, what initially may seem like a straight forward question—what makes a more walkable or pedestrian-friendly place?—has been actually answered in many different ways (Forsyth, 2015), leading to the current heterogeneous theoretical and operational groundwork of walkability research and policy.

Walkability is often defined as the extent to which the built environment supports and encourages walking and other pedestrian-related activities. Some authors identify specific elements that arguably make a place more walkable, such as continuously linked pavements, pedestrian crossings, sitting areas, street lighting and signage, as well as aesthetic factors and visual interest along pedestrian routes (Ewing and Handy, 2009). Others include a list of environmental characteristics that a place should provide, such as safety, comfort and convenience. In this regard, the "3Ds" approach defines walkability in terms of "density, diversity and design" (Cervero and Kockelman, 1997), later updated to the "5Ds" by including "distance to transit and destination accessibility," while the "7Cs" is based on the concepts of "connected, convivial, conspicuous, comfortable, convenient, coexistence and commitment" (Cambra and Moura, 2019).

The disparity in the term walkability can be further increased as the same characteristics are often considered differently. For instance, the recurrent term safety is often inconsistently defined among studies, as some refer to the risk of pedestrian-motor vehicle collisions, whereas others include hazards related to falls while walking and exposure to air and noise pollution. In addition, safety is sometimes considered from the perspective of crime in public space. Consequently, the actual definition of safety in a walkability policy strongly influences the specific determinants to consider in further interventions. For this reason, when the definition of the walkable environment includes intangible concepts, such as convivial or conspicuous, policymakers need to further elaborate on them to provide relevant and useful information for policy implication.

Despite the heterogeneity of desirable walkable environments, two main interventions on the build environment can be identified. The first one, based on the "3D" approach of urban density, diversity and design, requires the integration of land use planning and urban design to ensure walking proximity to certain destinations. The aim of these type of interventions is to plan a nonsegregated, dense and diverse urban land use distribution that offers a wide range of locations, activities and services to pedestrians, where the proximity to such places can be enhanced through continuous, well-connected and traversable pedestrian networks that include public transport to complement walking.

The second type of approach is based on physical interventions at streetscape level to improve pedestrian experience in terms of safety, comfort and pleasantness. This is often done by ensuring adequate, continuous and unobstructed pavements, safe pedestrian crossing and the availability of certain street furniture, such as sitting areas, street lights, and pedestrian signage, including accessible design for pedestrians with physical and mental impairments. Furthermore, these approaches often aim to minimize pedestrian exposure of traffic and to enhance positive characteristic and elements of the streetscape, such as enclosure, human scale and transparency, as well as the presence of urban green areas and public open spaces (GDCl, 2016).

Education and Encouragement: Raising Public Awareness on Walkability and Pursuing Behavioral Change

Apart from major investments to improve the walkable environment, there are a series of approaches known as “soft measures” or “smarter choices” to increase walking activity through behavioral change. They are intended to influence the perception of the general public to present walking as a feasible and desirable means of transport, especially for short trips or as a key opportunity within multimodal transport. This promotion of walking is often linked to the health, socio-economic and environmental benefits of commuting on foot when compared to other means of transport. They are not based on any legal sanction or reward and therefore individuals, business and public entities can opt to whether adopt them or not.

In the EU context, the European Mobility Week gives all Member States the opportunity to explore the role of urban transport and walkability concepts to tackle urban challenges. Since 2002, the EU provides campaign resources with an extensive repository of successful behavioral actions towards sustainable mobility (more info on www.mobilityweek.eu). Similarly, since 2011 the European Union grants the Access City Awards that recognizes a city’s willingness, ability and efforts to become more accessible for people with disabilities.

Enforcement: Regulations and Fiscal Measurements to Improve Walkability

Pedestrian-friendly places often require specific regulations to avoid conflicts between different means of transport and the urban land use allocated to each other, as well as to prevent unsafe and illegal behavior by drivers and pedestrians. Specific regulatory instruments can control the accessibility to certain vehicles to influence traffic conditions in parts of the urban areas with high pedestrian traffic. Another key measure is speed limitation and the distribution of urban land use for specific means of transport, with particular attention to on-street parking. In a more comprehensive approach, land use regulations require the assessment of new developments to comply with local travel plans.

Sustainable mobility plans often include fiscal measures to discourage private car use while incentivising active travel. These include economic incentives, compensatory schemes and social assistance through workplace, school and residential travel plans, as well as public transport subsidies to complement pedestrian mobility. Deterrents to private car users include pricing for parking and road use, as well as fuel and other car related taxation.

Evaluation of Walkability Policy and Planning

In order to design more walkable places and assess the impact of the plans, it is necessary to measure walkability and the actual walking activity, before and after an intervention. This information provides crucial input for further planning interventions and investment decisions.

Measuring Walking Activity and Experiences

Assessment methods to measure walking activity can be grouped in three categories, although they are often combined. First, direct observations are used to count the number of pedestrian passing through a street or entering a certain location. Second, indirect objective methods measure the frequency, intensity and duration of walking activity. These have been facilitated by smartphone technologies that allow for greater geographic and temporal detail. Third, direct subjective methods include survey questionnaires, interviews and walking diaries, which can be used to better understand walking behavior.

While walkability concepts were entirely assimilated among transport and urban planners at the beginning of the 21st century, there are still three major challenges to implement walkability interventions. First, walking is often ignored or not adequately measured in transport surveys, as a result walking is heavily underestimated and misrepresented. Second, current data collection methods differ widely, making comparability difficult. And third, collecting walking data is often time consuming and resource intensive, which presents particular challenges for accurate measurement. The International Walking Data Standard (Sauter et al., 2016) proposes a detailed set of requirements for walking data that are consistent and comparable, identifying five key performance indicators (see Table 2).

As the concept of walkability moved beyond the limited idea of walking as means of transport or moderate physical exercise, more walkability approaches linked to liveability studies focused on recreational walks as restorative exercise, cultural and socio-

Table 2 Key performance indicators to measure walking activity (Sauter et al., 2016).

1	Share of people who have made at least one walking stage on the survey day
2	Average number of daily walking trips per person
3	Average daily time walked per person
4	Average daily distance walked per person
5	Mode share of walking based on: stages, main mode, time, and distance

economic activities. Plans for recreational or leisure walking activities that quantify the use of public space by pedestrians are increasingly recognizing the importance of assessing not only walking activity but also pedestrian experiences.

Measuring Walkability

In order to measure the walkability of a place, it is necessary to first establish the theoretical and operational definitions of walkability, which are based on the objectives and specific characteristics of each initiative. These definitions guide the identification of the components and characteristics that determine the walkability of a place, which in turn can be observed and measured.

For large-scale components, such as terrain, urban fabric, land use, and pedestrian network, the most common methods include the interpretation and analysis of secondary data, like existing cartography, aerial images, and remote sensing. When the scale of analysis includes components and characteristics at a block or street level, the most conventional methods are pedestrian checklists, walkability audits, surveys, questionnaires, and interviews.

After all the necessary data have been collected, the final step is to process, interrelate and interpret it to assess the walkability of the area under study. There is a wide range of walkability assessment approaches, which could be broadly categorized in three main groups. First, some assessments exclusively focus on the urban fabric morphology. Second, walking accessibility assessments focus on the availability and spatial distribution of destinations within walking distance, including their characteristics and the ease of reaching them. And third, other assessments include and interrelate elements and characteristics of the walkable environment that influence walking activity and experience, to then calculate an overall walkability variable. They are commonly known as walkability composite indices (Hall and Ram, 2018), with a distinction between macro- and micro-scale assessments, the later known as walkability path indices.

Measure the Impact of Walkability Interventions in Walking Activity and Experience

Walkability interventions require an assessment of their effectiveness in influencing walking behavior. However, there is a current gap in understanding how the magnitude of a change in walkability relates to a change in pedestrian volumes and walking experience (Cambra and Moura, 2019). Some of the evidence remains methodologically weak due to the previously mentioned challenges related to lack of data on walking and the disparity of walkability assessments. Thus, it has become challenging to compare planning strategies, as well as generalize and validate results to support further policies. Aldred (2019) praises the use of quasi-experimental techniques, improvements in routine monitoring of smaller schemes, and the use of new big data source, while pointing out that more qualitative research could help develop a more sophisticated understanding of behavior change. As a good practice example, Cambra and Moura (2019) conducted a before-after walkability assessment using a validated methodology, opting for longitudinal analysis of the pedestrian volumes in the intervention sites and control areas, and quasi-longitudinal surveys on the walking experience in the area.

Conclusion

More people walking in pedestrian-friendly environments is increasingly being seen as a key policy objective to improve public health, promote more efficient and sustainable urban and transport planning, enhance community liveability and boost local economy. As a result, current regional and national policy strategies are setting an encouraging scenario for the development and inclusion of walkability concepts at local level to help in the improvement of sustainable walkable urban areas and prosperous pedestrian communities.

Walkability has become a ubiquitous and multidisciplinary policy topic, as walking and other pedestrian activities take place on a daily basis, but people decide whether to walk or not and how much they walk depending on personal attitudes and capabilities, environmental determinants, social norms and other behavioral controls. Consequently, walkability policies require a comprehensive approach to enable and encourage people to choose to walk by addressing specific physical improvements of the walkable environment, behavioral changes through education and promotion, and the establishment of fiscal, administrative and social measures to encourage walking while discouraging the excessive use of private car use, as well as sedentary and other unhealthy or dangerous lifestyles.

Introduction

Public transport in most parts of the world is both heavily subsidized and closely regulated, hence this chapter examines some of the key factors behind these two issues. In many senses, the need for subsidy and regulation lies at the very heart of the planners vs. the market dichotomy in terms of the provision of all transport services, not just those relating to public transport. In particular when operated along purely free market principles, this results in a multitude of issues, primarily due to the fact that such markets suffer from a high degree of market failures. While the term “market failure” can be very clearly defined, in this context we simply describe it as occurring where the market mechanism does not come up with the “right” answer. This is specifically in terms of allocating the appropriate user to the appropriate mode. It therefore requires intervention by government bodies (mainly in the form of transport authorities) to coordinate and plan such activities in order to correct or reduce the effect of such failures. This intervention can come in the form of direct provision (the government does it itself, such as is the case with education), financial (subsidy) or direct command (regulation), or some permutation of all three. This chapter therefore will concentrate on the last two mentioned and outline the main reasons for such market failures and hence the mechanisms used to correct for these.

Rationale for State Intervention in Public Transport Markets

Before measures of either subsidy or regulation are implemented in public transport markets, there needs to be a clear rationale for such interventions. As stated, this is due to the existence of market failure, and primarily that the market undervalues public transport. This is for a number of reasons, all of which can be related to the key roles played by public transport in modern society, which are listed below.

Participative Requirement/Transport Poverty

Not everyone in the country either owns or has access to (as a driver or passenger) private transport i.e. the car. The UK 2018 National Travel Survey (DfT, 2018) for example showed that 24% of households had no access to a car. More concerning, car availability has been found to be strongly related to income, with earlier travel surveys showing 47% of those on the lowest quintile lived in a household with no car, compared to a mere 8% in the highest quintile. Furthermore, 50% of single parent families did not have any access to private transport. Even these figures however tend to underestimate the scale of the problem, as they mask those individuals who may live in a household that does own a car, but one which is in constant use by another household member. Access therefore is still a major issue.

Public transport supports Barr's idea of transport as a "participative requirement" (Barr, 2020), that is, it is required in order to fully participate within society. Education is a similar need, where a lack of education (at a basic level) will not kill you but may make it difficult to "get on" in the world. Contrast this with an "absolute requirement," which relates to food, shelter and health services, which represent essentials for continued wellbeing. With a participative requirement however, the basic assumption is that some kind of minimum provision is required. In other words, not everyone needs an Oxbridge education and a Rolls Royce but rather access to some minimum level of provision, which in the transport context is normally fulfilled by public transport.

This also links into the idea of "transport poverty," which as Lucas (2018) highlights, arises from one of four/five factors; personal/general availability, economic barriers, time poverty and the available options are considered to be unsafe. In terms of mobility, public transport may be viewed as a participative requirement that can even alleviate transport poverty. Subsidizing such services can also be viewed as a progressive measure. Bueno Cadena et al. (2016) found that the effect of a highly subsidized public transport fare policy in Madrid resulted in greater uptake from those residing in poorer, rather than more prosperous areas of the city. On social equity grounds therefore, this provides a strong rationale for it to be subsidized.

Use of Land Space

At certain points in the day (and in some severe cases at all times during the day), there is an over provision of private vehicles on particular sections of land, that is, roads. Roads have a limited capacity, which in many instances is exceeded. This in turn creates congestion. In some sense, congestion purely on its own is not a problem as this is a private decision. In other words, if an individual chooses to sit in a traffic jam every day on the way to and from work, then that could be viewed as a choice and one they are free to make. In this context however, the problem is that congestion costs money in terms of loss of working time and is therefore economically detrimental. Estimates from Smith et al. (2016) suggest that traffic congestion costs the UK economy £8.4bn every year, with the DfT (2014) estimated a congestion cost of £1.9bn on the strategic road network alone. In simple terms, the efficient working of the economy is dependent upon an efficient transport system, that is, one that actually moves people and freight. Moving people in larger sized groups takes up less land space, either on a bus, LRT, metro, or a train, and hence reduces congestion. Based on a study in Melbourne for example, Nguyen-Phuoc et al. (2018) found that the withdrawal of all forms of public transport would increase the number of severely congested roads to almost 150%, resulting in gridlock across large areas of the city. Given the context, these may be considered to be very much low side estimates of what the general case would look like.

Reduced Environmental Impact of Mobility

Partly related to congestion, this concerns the more general issue of the adverse impact of travel on the natural environment and hence how this can be reduced. Creutzig and He (2009) for example highlight that transport was responsible for 23% of world energy related greenhouse gas emissions, with 74% of that total as a result of road vehicle usage. While it is difficult beyond the naive view to highlight public transport's role in this debate, Hensher (2008) in running a number of policy scenarios designed to reduce transport's overall contribution of greenhouse gas emissions, highlighted publicly funded investment in public transport as a key area. Without such investment, any proposed policy induced change would simply result in a short-term behavioral change and a gradual drift back to the status quo. Public transport therefore offers the possibility of reducing individual carbon footprints and provide more sustainable transport modes on a mass scale.

Safety

Private cars represent a hazard to personal safety, particularly those that travel closely together. Although slightly dated now, figures from Evans, (2003) show that in terms of accidents per kilometer traveled, the train is twice as safe as the bus and the bus twice as safe again as the car. To a certain extent however, this aspect has to be treated with a deal of caution, as there may be a trade-off between the speed of private transport and the safety of public transport—slower vehicles cause less injuries and fatalities. Nevertheless, it is easier to manage the overall safety of a given transport system if individual movements are combined on a larger scale, as this allows a tighter degree of regulation and coordination of movement. In the case of mainline rail infrastructure, for example, every movement is controlled by signal, hence significantly reducing the risk of collisions.

The Mohring Effect

More academic arguments for the payment of subsidy are based around the idea of "welfare benefits," with Xu et al. (2018) highlighting how this would transmit into usage through a theoretical stance based upon the Mohring effect (Mohring, 1972). This suggests that increasing the frequency of public transport services will reduce generalized cost for users in the form of decreased waiting times, and hence lead to an increase in the demand. In some senses, this is akin to the idea of the virtuous circle. This is evidenced by Jara-Diaz and Gschwender (2009), who found that making users bear the whole cost of public transport provision, i.e. unsubsidized, results in a reduction in frequency regarding its optimal social level; in simple terms, less is provided than is socially desirable. Hence subsidy is required to ensure the socially optimum level of provision. To that argument it can be added that in more contemporary times potential users of public transport services are unwilling to pay the full cost of the provision of such services to the standards they would expect. The only way this gap can be bridged, and hence any form of Mohring effect realized, is through the payment of subsidy. In some respects this is akin to White's argument (White, 2010), that higher levels of usage will result in higher subsidies being paid, not lower, the recent experience in London being a classic example (DfT, 2019).

It should be noted however, that Xu et al. (2018) also highlight stances that suggests the Mohring effect is far more restricted. Notably, they cite Hensher (1998), who suggested that lowering service fares through subsidy only had a marginal impact on public

transport modal share and also [Savage \(2004\)](#), who put forward the commonly held view that the payment of subsidy leads to inefficiencies and general management slack, hence largely offsetting any potential gains.

Forms of Revenue Subsidy Payment

The most basic division of forms of subsidy would split these into two, capital and revenue, the former where subsidy is targeted at capital investments and the latter operations. This section will only consider the second of these, which are primarily aimed at reducing the operating deficit between revenue and costs. In many senses, the form of revenue subsidy which is used reflects the institutional framework under which public transport is provided. In contemporary times how this subsidy is paid has become far more formalized, again reflecting changes in the institutional framework. Specifically subsidy payment arrangements have been put on a far more statutory basis between state and provider, whether the latter be a public or private sector organization. Previously, [ESCAP \(2003\)](#) highlighted that in the case of state railways, these were often legally required to meet any demand (both passenger and freight) at fixed prices, with no binding provisions for any compensatory payments, that is, subsidy. In terms of the European Union, Regulation 1191/69¹ was an early piece of legislation that introduced the idea of public service obligations (PSO) in recognition of the requirement placed on an operator to provide an (unprofitable) public service. For such services, the operator would then be entitled to compensation from the specifier of the PSO, normally a transport authority.

In terms of the available options, revenue subsidy can be allocated in one of three ways:

- direct award (deficit financing)
- through a competitive tender process (absolute and relative contracts)
- negotiated contract

As the name suggests, direct award is where the subsidy is paid directly to a single provider and has normally been in the form of deficit financing. [Matulova and Fitzova \(2018\)](#) for example give a good overview of how this actually “operates” with reference to the Czech urban public transport sector, where most (still publicly owned) operators receive a form of loss compensation based upon a PSO. This includes an element of profit in order to retain the required technical conditions, although in practice profit levels for most operators have been set at zero. The operator therefore negotiates directly with the transport authority in relation to services to be provided, the fares to be charged and the investments required to support such operations. The financial deficit this produces is then paid as a form of subsidy.

In competitive tendering, the service specification is drawn up by the transport authority and then put out to tender. Most will specify the frequency and fare to be charged but may still leave some freedom with regard to vehicle standards and the general development of the service over the period of the contract. In other cases, tenders can be very specific as regards all service elements, such as in London. Due to the tightness of such tenders, the lowest bidder is most commonly awarded the contract. Competitive tendering has been in place in several parts of the world for many years, hence difficult if not impossible to give an overview of the main issues in a single chapter. Interested readers are therefore directed to the long running Thredbo series of conferences (see, e.g., [Alexandersson et al., 2018](#)), where many of these issues have been discussed and developed.

Generally speaking, tendering processes have very high transaction costs, hence can be expensive. A further issue is that it can result in an inconsistency in the provision of services, with operators unwilling to heavily invest (both financially and in terms of corporate identity) during the period of the contract. This is why [Hensher and Wallis \(2005\)](#) see a role for negotiated contracts, particularly where the incumbent is recognized as an efficient provider, a greater focus needs to be placed on innovation to grow patronage and incentives need to be provided to encourage the investment to support such activities. Such arrangements would also negate the high transaction costs and reduce business uncertainty associated with contract work, thereby unlocking potential investment opportunities.

Having considered the main issues behind the subsidization of public transport, we now examine the issue of regulation.

Regulation of Public Transport

Regulation, in the general sense, comes in two main forms, either qualitative or quantitative, the latter often described as economic regulation, with the main divisions in the public transport context shown in [Fig. 1](#).

Qualitative Regulation

Qualitative regulation is primarily focused on licensing, and hence in the context of public transport, ensuring that all vehicles are “safe” and fit for purpose, drivers are competent to a set minimum level to operate such vehicles and those responsible for operation are professionally competent to ensure that operations are carried out in a manner that meet minimum safety standards. Without such regulation, we would have market failure, due to the issue of a lack of “perfect information.” Hence to give a very simple example, a bus user does not need to be a highly qualified automotive engineer in order to assess if the bus they are about to board is “safe,” as the regulatory framework performs that function on their behalf. The same is true of the abilities of the driver. Hence, users can use such services in the knowledge that all aspects of operation conform to some minimum standards that are deemed to be “safe.” In the absence of any quantitative regulation, then any operator meeting these minimum standards is licensed to operate

¹ All provisions of Regulation 1191/69 have subsequently been superseded by EU Regulation 1370/2007.

Figure 1 Main forms of regulation of public transport services.

public transport services. Note however that in some instances, transport authorities may specify criteria that are above the legal minimum, either to ensure the use of higher quality vehicles, or for some other (wider public interest) purpose; Transport for London for example require all buses to be painted red irrespective of the brand of individual operator of the service, as red buses are synonymous with London. In most countries, there will be a specific government body that ensures all such standards are upheld, and in the case of the UK, this comes under the remit of the Traffic Commissioners. Any breach of rules by operators may result in financial penalties or ultimately the suspension or complete withdrawal of the licence.

In many if not most developing countries, there is what is generally referred to as the “informal sector,” for which a very simple definition would be that public transport services are provided by small private operators without any form of regulation or other official endorsement (Chavis and Daganzo, 2013). While such a framework does provide some advantages, the main drawbacks have been identified as low vehicle and passenger convenience standards, poor safety records and significant contributions to environmental and congestion externalities (Venter, 2013). In many respects, all of these problems underline the need for qualitative regulation in the provision of public transport services.

Quantitative Regulation

Quantitative regulation on the other hand relates to placing conditions on the operator with regard to economic behaviour in the market, hence such controls can be applied with regard to the fare (or maximum fare) to be charged, the minimum frequency to be operated, the specific routes to be run and those “allowed” to operate those routes. In all such cases, this will be necessary because in the absence of such restrictions, operators would be in a position where the profit motive would outweigh the wider public interest. This generally occurs where there is a monopoly provider, that is, another example of market failure. Hence, the role of quantitative regulation is to ensure that public transport services are provided and consistent with the public interest, and not purely on the basis of (short term) profit.

Ideally, such measures should be overseen by an independent industry regulator, which has led some to observe that the “rise” of the regulatory state should provide for a depoliticization and depublicization of control of the regulated industry (Majone, 1997). As a consequence, the industry, in this context public transport, can be run to meet the wider needs of the public interest without being influenced by political considerations.

In terms of regulatory measures, we will only consider those relating to the fare to be charged, with the main instruments used outlined below.

Set the Fare

This is the simplest, and perhaps the most commonly used, form of fare regulation in the provision of public transport services, with numerous examples from across the world. The setting of the fare is illustrated in Fig. 2.

Figure 2 Fare regulation, set the fare.

Fig. 2 shows a generic market for public transport services, hence as the fare decreases, more will wish to travel by this service, shown by the demand curve (D), and as the price rises, more operators will be willing to provide services, shown by the supply curve (S). Where the two meet is known as market equilibrium, hence in this example this would give a market price of P_m , with the level consumed at Q_m . For one or more of the reasons previously outlined, this may be viewed as “too low” a level from a social welfare perspective. In order to encourage usage therefore, the regulator specifies a lower price, in this example P_r . Note that in order to be effective, that is, achieve wider public interest goals, any regulated fare needs to be set below the market fare.

One reason for fully illustrating what may appear to be a very simple concept is that without any further action, at the regulated fare demand would increase to Q_{Dr} but operators would only be willing to provide, that is, find it financially viable, quantity Q_{Sr} . This would result in massive overcrowding and completely unmet demand, which in a normal market situation would be addressed through increasing the price. With a regulated cap however, this cannot occur. Other inventory measures therefore need to be taken. In this case, this would normally be in the form of paying operators a subsidy in order to enable an increase in the level of supply to occur and to meet the demand at the regulated fare. Hence, subsidy and regulation are very much linked as part of an overall plan of public intervention.

Set Changes in the Fare

Rather than specify the actual fare to be charged, regulation can be in the form of specifying the amount the fare can change from one year to another. This is normally done in relation to the level of inflation, originally put forward by Littlechild (1983) in the form of RPI-X%, hence the retail price index (i.e., inflation) minus a factor specified by the regulator. In terms of public transport, this has been commonly applied in the case of passenger rail (Mirrlees-Black, 2014), a framework that has been in place over the full 23-year period of British private sector operation. One issue with such an approach, and particularly prevalent in the UK rail example, is that it assumes price differentials do not need to change over time, and hence by implication, were set at the “correct” level when the regulation was introduced.

Specify the Rate of Return (Profit) to be Gained

Rather than stipulate the fare or the change in the fare, the regulated price can be based on a rate of return. Hence over the regulatory period, all costs and investment needs are assessed, a profit rate is added, and from demand forecasts a fare level can be specified. This has been extensively used in the regulation of the British rail infrastructure provider (Network Rail), hence all operating costs and investment needs are appraised over a five year “control period,” and track access charges set accordingly to deliver the specified rate of return.

Problems with Regulation

Regulatory reform, and arguably regulation in general, has been described as often seen as a road paved by good intentions, but leading to “policy hell” (Lodge, 2002). Why this is the case is because the whole concept of regulation is to attempt to correct for some market failure, hence the planners intervene in the market to produce the “right” outcome. Through such endeavors however, this can introduce a wide variety of other issues. These were best summarized by Cowie (2010) as the only problem with regulation is the fact that it is needed at all. All of the following factors are extensions of this basic idea.

Limits Free Enterprise

von Mises (1949) put forward the theorem of consumer sovereignty, which to summarize, states that those firms that best serve the consumer are the ones that prosper the most. In many ways, this is the whole premise of the free market. Any regulatory framework restricts what the “market” can achieve. Hence as examples from the public transport context, restrictions on market entry may prevent the development of innovative new routes, while fare regulation may preclude the introduction of any user focused ticketing options. Innovation therefore is stagnated, and hence rather than consumer sovereignty, what results is regulatory authorities’ perspectives of what is in the best interests of the consumer, which can be quite different. The basic argument therefore is that regulation tends to lead to conservatism in the provision of public transport services.

Always a Second Best Solution

Regulation will always be a second-best solution, the “best” solution being viewed as the market. Given the full set of assumptions of perfect competition, the market will ensure that prices are as low as possible in order to ensure consumers maximize benefit and firms make a fair return (i.e., normal profits) which leaves sufficient funds for investment. The market also ensures efficiency in production, as inefficient firms will be driven out of business. All of these factors are reduced in a regulated market, as market mechanisms are subsumed by the regulatory framework, which will never be as efficient as the former. It can in some extreme instances offer protection for inefficient operators.

Asymmetry of Information

Cowie (2010) highlights that in order to regulate an industry effectively, the regulator requires a high level of data in order to plan and control operations. That data however is generated by those they are attempting to regulate, hence the operator knows more about their own business than the regulator does. Combined with cumbersome regulatory procedures (i.e. bureaucracy), this can lead to ineffective measures being used, and even where these may better reflect the reality of the situation, such measures may be easily avoided, with the consequence of regulatory frameworks becoming ineffective.

Regulatory Capture

Stigler (1971) put forward the idea of regulatory capture, which is a generic term to describe the situation where the regulator acts in the interests of the industry rather than in pursuit of wider public interest goals. This can be for a multitude of reasons. “Capture” need not reflect capture by the industry, but can also refer to the situation where the status and importance of the regulator rises with the importance of the industry, hence measures instigated by the regulator are not as “tough” on the industry as would be consistent with the public interest. Again therefore, the regulatory framework becomes ineffective.

Concluding Remarks

This chapter has examined the issues of subsidy and regulation in the provision of public transport services, in which the main principles behind such actions have been outlined. Primarily, both measures lie at the very heart of the market v the planners dichotomy, with government intervention in whatever form targeted at correcting for failures associated with provision strictly along market principles. Such issues however are closely associated with the very basic idea of what should be provided by the state and what should be left to individual responsibility, and to what extent such actions are supported by public funds.

Public transport is the only viable mass mover, hence a key element in reducing the detrimental impacts of mass mobility on both modern society and the natural environment more generally. It cannot do so however along purely market-based principles, as this results in high elements of market failure, particularly an under valuation of such services. Intervention, in the form of subsidies and regulatory measures, are required to produce a social welfare maximizing outcome. In other words, one that ensures the allocation of transport services results in the use of modes, particularly public transport, that are far more consistent with the idea of the wider public interest rather than one based solely on private benefits.

Biography

Jonathan Cowie is a lecturer in transport economics at Edinburgh Napier University, where he teaches masters level modules on public transport, transport policy and transport economics and appraisal. His research interests are best summarized as the supply side economics of transport markets, and he has published numerous articles on bus and rail economics. Jonathan is author of the book *The Economics of Transport*, and a longtime member of the Scottish Economic Society and the Chartered Institute of Highways and Transportation.

Urban Regeneration Strategies

For decades, both researchers and practitioners have acknowledged that transportation and urban development are inextricably interwoven. Despite this awareness, a recurrent theme is that transportation and urban planning are still separate worlds. To overcome this lack of integration, many attempts have been made to understand the causes of this separation, and concepts have been developed to close the gap. This situation is clearly visible in the wave of urban regeneration since the late 1980s.

Urban regeneration is usually associated with a more positive attitude toward cities, following a period when cities were predominantly perceived as problems. As the geographer PJ Taylor once stated: “‘Urban problems’ dominated urban research in the second half of the 20th century to create what might almost be termed a ‘hate literature’ on cities.” (Taylor, 2004, p. 3). Following decades of car-based suburbanization and massive job losses in inner-city areas, cities had developed into concentrations of unemployment, crime, poverty, and decay. While the prime focus has been on Western cities, urban areas elsewhere did not obtain a better rating.

In the decades preceding urban regeneration in the strict sense, renewal and redevelopment programs in the 1960s and 1970s invested in deprived neighborhoods. The emphasis was on the improvement of the conditions of the urban poor and on physical redevelopment. In contrast, since the 1980s, an entrepreneurial policy discourse has emerged with competitiveness and social cohesion as leading principles (Furbey, 1999). Urban regeneration is thus a historically specific concept, and is associated with the increased attractiveness of cities, both in discourse and practice. This has also been labeled “urban renaissance”, and one of the characteristics is that policymaking at the urban level has gained importance viz-a-viz the national level.

In particular since the early 1990s, a number of cities have become iconic examples of urban regeneration in which the bad image of urban decay was replaced by a view of cities as hotspots of creativity, cosmopolitanism and prosperity. The organization of the 1992 Olympics in Barcelona was accompanied by a regeneration program with, among other things, major investments in public space (Fig. 1). Five years later, in 1997, a Guggenheim Museum was opened in Bilbao, Spain. The building was designed by architect Frank Gehry and appeared in magazines all over the world. These are two leading examples of culture-led urban regeneration, and both large and small cities around the world have tried to copy the Barcelona model or the Bilbao (or Guggenheim) effect (González, 2011). In general, this type of urban regeneration reflects the transition from an industrial to a services-based economy, with a discursive emphasis on creative industries such as art, design, advertising, and film. Not only are these activities considered important economic sectors, they are also seen as magnets for investments by other sectors. Culture-led urban regeneration strategies have been accompanied by investments in transportation infrastructures and public spaces. Nevertheless, mega-events and architecture attracted more attention, and also the British regeneration policy in the 1990s paid only limited attention to transportation infrastructure (Dabinett et al., 1999).

Sustainable Mobility and Regeneration

While transportation has not always been the main focus in urban regeneration policy discourse, there have been many interactions between these two worlds. Particularly in France and some neighboring countries, the development of High-Speed Rail networks since the 1980s was linked to regeneration investments in and near stations. In line with culture-led urban regeneration strategies, several railway stations were designed by leading architects. But urban regeneration and transportation have been integrated in a more profound way than the merely architectural.

The urban regeneration discourse is a contemporary of that on sustainable mobility. Unsurprisingly, the two have important commonalities, and interacted significantly. A common theme is how pedestrian zones, bicycle infrastructure, and inner-city public transportation contribute to make city centers more attractive for residents, tourists and employees, in particular in the service industry. While in many regions, tram and railway networks had been reduced in the decades following World War II, particularly

Figure 1 With the organization of the 1992 Olympics, Barcelona became a best practice for urban regeneration strategies around the world (the Montjuïc Communications Tower designed by the famous architect Santiago Calatrava).

Figure 2 Light rail and trams have become a key ingredient in sustainable urban development programs (the Vauban district in Freiburg).

the 1990s and following decades witnessed investments in trams, light rail, tram-trains and similar systems. Often-cited examples include Strasbourg and Nantes in France, and Freiburg and Karlsruhe in Germany (Fig. 2). These examples show that sustainable modes of transportation can be (re)introduced.

Notwithstanding the possibility of reintroducing transportation modes and changes in policy, planners promote a decade-long, sustained strategy to integrate land use and transportation planning (Hickman et al., 2013). The prime example in the literature of

such a sustained strategy is the continuity between the 1947 Finger Plan in Copenhagen and more recent policies that locate urban development alongside transit lines (Knowles, 2012). The ‘fingers’ are the corridors or development axes which have their origin in the city center.

Especially in the United States, the smart growth and new urbanism movements in design have been successful advocates of urban regeneration. Transportation is a key dimension of these approaches which promote compact, walkable, mixed land use neighborhoods as an alternative to urban sprawl, in line with the 3Ds of travel demand: Density, Diversity, and Design. The first D, Density, enables efficient investments in transit as well as easy access to many activities at walking distance, as does the second D, Diversity or mixed land use. The third D, Design, is important to make the environment suitable for walking (Cervero and Kockelman, 1997). According to the website NewUrbanism.org the aim is “Giving people many choices for living an urban lifestyle in sustainable, convenient and enjoyable places, while providing the solutions to peak oil and climate change” and this is followed by the equation “Renewable Energy + Electric Transportation + Walkable Urbanism” (“New Urbanism,” n.d.). This illustrates that transportation is a key component of new urbanism and smart growth.

Transit-Oriented Development

Since the rise of urban regeneration strategies, proposals to integrate transportation and land use have matured and have inspired practitioners and researchers all over the world. Transit-Oriented Development (TOD) is presumably the most influential model in this respect. TOD encompasses that urbanization is concentrated around transit stations. The areas in the vicinity of stations are walkable neighborhoods with high densities in particular within the half mile radius of a station. TOD has its origins in North America, but has traveled from there to research institutes and planning offices in Europe, Australia, Asia, and elsewhere (Ibraeva et al., 2020).

Within the TOD approach, not all station areas need to be developed in the same way. The aim is to balance the quality of transit services and the activities in the area around the station. This idea is translated into the node-place model (Bertolini, 1999). The node value indicates how accessible a location is in transportation terms and, as a consequence, emphasizes the connectivity with other locations in terms of frequency and travel time. The place value is a measure which indicates the diversity and intensity of the activities performed in the area surrounding the node. Fig. 3 shows the different possible (im)balances between node and place value.

Experiences Around the World

Policy strategies such as TOD, culture-led urban regeneration, and compact city development travel around the world and are part of a global planning discourse. Attempts to link mega-events like the Olympic Games or soccer World Cup to urban regeneration could be found in locations as diverse as Cape Town, Rio de Janeiro, Beijing, and London. As mentioned earlier, TOD is particularly influential in the US where the concept was developed before it spread all over the world. However, every city is unique and strategies materialize differently in different locations.

Figure 3 The node-place model. Source: Based on: Bertolini (1999), p. 202.

Figure 4 In the design of Houten, the Netherlands, bicycles have priority over other vehicles.

The expansion of High-Speed Rail and the strategy to develop stations as engines of growth is mainly observed in Western Europe, and later on, in China. Note that the 1964 Tokyo Olympics and the opening of the Tokaido Shinkansen high-speed rail connection between Tokyo and Osaka the same year predate urban regeneration in the strict sense. In many European cities considerable investments have been made in trams, tram-trains and light rail systems, but Europe has by no means a monopoly on such systems. Many examples of light rail predate urban renaissance but have been refurbished and extended since the wave of urban regeneration.

In Latin America, Bus Rapid Transit (BRT) is the most well-known vehicle for urban development. Although separate bus lanes and corridors require substantial investments, BRT is cheaper when compared to rail-based transit. Dedicated, segregated lanes, right-of-way infrastructure, and modern vehicles contribute to comfortable, fast, and frequent transportation. The rise of BRT systems runs in parallel with a more positive attitude toward cities in Latin America, which challenges the commonly made association between urban areas and crime. Examples of cities with a BRT system are Curitiba (Brazil), Bogotá and Cartagena (Colombia), Quito (Ecuador), Lima (Peru), Guadalajara (Mexico), Buenos Aires (Argentina), and Santiago (Chile). And also outside Latin America, BRT was implemented in places like Johannesburg (South Africa) and Guangzhou (China). While competitiveness generally is a leading concept in urban regeneration and transportation planning, Latin American BRT policies often emphasize equity and the role of transit in delivering accessibility to vulnerable population groups (Mejía-Dugand et al., 2013).

In the context of urban regeneration, the cornerstone of transportation planning is transit. However, station areas are dependent on the surrounding area. That is the reason why the creation of walkable neighborhoods is an inherent part of TOD and similar strategies. Apart from increases in sidewalk width and the provision of safe crossing facilities, cities have established car-free streets. This is part of what has been called the pedestrianization movement which involves the transformation of city streets into places where people can walk safely and comfortably. Organizations like Walk21 promote these measures via conferences and other activities (Walk21, 2020). Besides walking, the bicycle is promoted as a sustainable and healthy mode of transportation, but not in all locations. Topography, climate but also cultural reasons may explain why biking is less universally promoted than walking. Common bicycle-promoting measures include the provision of bike lanes, storage facilities, especially near stations, and bike share systems, which can be seen as an indicator for urban regeneration. Copenhagen and several cities in the Netherlands act as sources of inspiration for bicycle-oriented policies (Fig. 4).

Investments in transit and the promotion of walking and cycling are one side of the transportation planning coin, the other side is the discouragement of car use. This corresponds to the idea that policies need both sticks and carrots to transform urban transportation. The implementation of road pricing in the form of urban cordon charges is a “stick” to discourage car use which is intensely discussed (Eliasson, 2014). Examples of urban road pricing can be found in Singapore, Stockholm, and London. While the focus of pricing is on congestion mitigation, the aim is also to make cities more healthy and livable, which is also the aim of Low Emission Zones where the most polluting vehicles are not allowed to enter. Related measures include parking restrictions, traffic calming and banning motorized vehicles in some streets (Nieuwenhuijsen and Khreis, 2016).

Challenges and Criticisms

Emphasizing the need to integrate land use planning and transportation policy has been a constant in the literature. The associated challenge is to foster cooperation between stakeholders, in particular planning authorities, public transportation operators, but also developers. The financial dimension is of prime importance. The development of transportation infrastructure requires high initial

investments, and the same holds for land acquisition and large scale real estate developments. These investments may be offset by higher property prices near public transportation stops. Various value capture mechanisms have been proposed to ensure that benefits not only flow to developers, but also to those who invest in the infrastructures.

The effect of TOD-like as well as other types of urban regeneration strategies on real estate prices is a popular topic of study, but most attention goes to the effects on travel behavior. Besides transit use, the level of walking is a key indicator. Given the diversity of settings, densities, and contexts, it is not possible to provide universally applicable effect sizes for car use, transit patronage or the share of walking. Looking at this issue from a different angle, some actors do not classify projects as TOD when the share of sustainable travel is below, for example, 50% (Ibraeva et al., 2020). Regarding the effects, residential self-selection complicates the estimation since people with a positive attitude towards transit and walking have a preferences for living in walkable environments with good transit access (Cervero, 2007).

What TOD, BRT, compact city, sustainable mobility and culture-led and other urban regeneration strategies have in common is that such concepts have become part of an international planning discourse in which best practices from cities around the world are used to promote a better integration of transportation and land use planning. However, concerns have been raised regarding the transferability of policies originating in different contexts (Thomas et al., 2018). International policy discourses highlight in the first place factors which are easy to measure or visualize. Clear examples of easily transferable elements include population and job density, transportation technologies, and the half-mile radius around transit stations. The implementation of universally applicable models may result in cartographic reductionism and a static view of place which ignore the complexity inherent to particular places (Qviström et al., 2019). Furthermore, a restricted focus on station areas can turn the focus away from wider social effects.

A common concern with urban regeneration is gentrification. Investments in public space, housing, and transportation infrastructure generally increase the attractiveness of neighborhoods. As a consequence, rising property prices often displace the original residents, and the characteristics of the refurbished neighborhoods may no longer serve the needs of the original population. This is, for example, the case when investments in office buildings and connections to business districts are made in a largely working-class district. Urban regeneration strategies illustrate how well-intended policies to do something about urban decay, necessarily promote particular groups and ways of life (Enright, 2013). The wave of urban regeneration and TOD strategies discussed here clearly reflects the growing importance of the service sector in urban areas.

Introduction

The way in which we move around has profound impacts on society, the environment and the economy. Social impacts relate to any impacts that the transport system has on people. These impacts can be positive, for example providing access to essential services, social connections, providing physical activity and enhancing wellbeing. At the same time there are a broad range of negative impacts associated with mobility. Around 1.35 million people die each year as a result of road traffic injuries ([World Health Organization, 2020](#)) and many more are injured or traumatized by the impacts. Transport related emissions are a major contributor to climate change and local air quality, which both impact human health and wellbeing. Car dependence is associated with sedentary lifestyles and inactivity, contributing to rising levels of obesity and poor physical and mental wellbeing. Transport also constitutes a substantial proportion of household budgets which can be a cause of financial distress.

A broad range of transport related social impacts have been considered in academic literature and in practice. [Jones and Lucas \(2012\)](#) suggest that these fall into five broad categories:

- Accessibility (potential)
- Movement and activity (realized)
- Health related outcomes (road casualties and injuries; air quality; noise; physical activity; intrinsic value; mental health)
- Finance related (affordability)
- Community related (social interactions, personal safety & fear of crime, forced relocation).

Differences in the way different groups in society are affected by transport policies or interventions are known as distributional impacts. Considering the distributional impacts is important when considering transport equity or fairness.

In general, better off populations benefit most from current transport systems, while also inflicting most harm on others ([Brand and Preston, 2010](#)). The level of accessibility provided by the transport system and land use varies spatially and according to socio-demographic characteristics, such as income, disability, gender, age and ethnicity. Those that face difficulties accessing goods and services because of poor transport can be at risk of transport related social exclusion, with adverse consequences such as unemployment, missed appointments, poor uptake of education, difficulties in accessing healthy food and social isolation ([Lucas and Jones, 2012](#)). Negative outcomes, such as respiratory diseases, chronic health conditions and road trauma associated with the transport system are felt differently by different social groups, both within and between countries. For example, 93% of the world's road traffic fatalities occur in low or middle income countries, despite only owning 60% of vehicles in the world ([World Health Organization, 2020](#)). Poor air quality and transport crashes are more prevalent in more deprived areas ([Schweitzer and Zhou, 2010](#)). Breathing the air in the 1m above surface height exposes people to higher concentrations of air pollution from traffic meaning that children, especially those in pushchairs are particularly impacted by traffic pollution ([Sharma and Kumar, 2018](#)). Globally, indigenous populations have benefited least from the mobility provided by high carbon transport systems and are least responsible for associated emissions yet are often most vulnerable to climate change ([Markkanen and Anger-Kraavi, 2019](#)).

Transport policies and interventions have a fundamental role to play in ensuring that the transport system achieves positive outcomes for all members of society. It is important that decision makers consider how a proposed transport policy might impact people (social impacts) and how these impacts will be distributed across society (distributional impacts).

For some nations, the recognised rights and entitlements of people under international and national human rights or equalities legislation has resulted in distributional impact assessment approaches focused on those with protected status. For example, in the UK, national and local transport authorities must adhere to the Human Rights Act 1998, which incorporates articles of European

Convention of Human Rights (EHRC). The Public Sector Equality Duty (PSED) set out under section 149 of the UK Equality Act 2010 (UK Government, 2020) requires public bodies to pay due regard to impacts of policies, plans and projects with regard to groups of the population with 'protected characteristics'. These protected characteristics are age, sex, disability, religion, race, marriage/civil partnership, sexual orientation, transgender and pregnancy and maternity. In many countries the rights of indigenous peoples are recognised through the United Nations Declaration on Human Rights (United Nations, 2007). Such nations have a commitment to incorporating equity and rights of indigenous peoples in all decision making processes and that should, but often does not, extend to transport decision-making.

Social impacts have not been considered in transport appraisal to the same extent as economic or environmental impacts (Anciaes and Jones, 2020). A failure to consider social impacts has contributed to the negative impacts we see arising from the transport system, and unequal distribution of these impacts. Social and distributional impact assessments in transport planning and policy are therefore important from a social justice perspective, helping to redress existing social inequities and ensuring transport investment is fair and achieving positive social outcomes, rather than inflicting harm.

This article discusses some key principles for social assessment and an outline of social and distributional assessments for transport intervention. A Highways England case study describes how a bespoke tool is being used to capture the equality impacts of new major highways schemes. The article ends with an overview of some of the key challenges to assessing social and distributional impacts.

Social and Distributional Impact Assessments

A variety of approaches to measuring social impacts exist through national transport appraisal guidelines in many countries. However, they often do not adhere to all of the principles (Fig. 1) and are often considered an "add on" to existing cost-benefit analysis frameworks, and approached as a technical exercise. It can often be difficult to ascertain how much of a bearing social impact assessments have on decision making, relative to monetised impacts included in a cost-benefit analysis (Hickman, 2019).

Fig. 2 provides an outline process for social impact assessment within transport policy. Existing social problems and issues should be identified (Stage 1) prior to formation of relevant transport policy (Stage 2). However, in practice, social impact assessment is more often integrated into the policy process at Stage 3 (once a project or policy has been proposed and at the option appraisal stage) rather than informing new transport projects or policies.

Stage 3 focuses on assessing social impacts of the transport policy or intervention. The types of social impacts assessed varies across nations and institutions. For example, the English transport appraisal guidance, WebTAG assesses the following social impacts: physical activity, security, severance, journey quality, option values and non-use values, accessibility impacts, and affordability impacts (DfT, 2019). Australia has on guidance on qualitatively assessing impacts of transport projects on accessibility and affordability (Anciaes and Jones, 2020). Waka Kotahi - New Zealand Transport Agency has a Social Impact Guide, which identifies a number of social impacts: air quality, noise, vibration, water quality, (changes to) transport modes, social connectedness, community severance, changes to facilities, changes to local movement patterns, safety, economy or public health (Waka Kotahi NZ Transport Agency, 2016).

Principles of Social Impact Assessment

1. To ensure more sustainable and equitable development. Impact assessment should promote community development, capacity, and social capital.
2. SIA should take a proactive approach to achieving better outcomes, rather than simply seeking to mitigate negative or unintended outcomes.
3. SIA should inform the design of the policy in an adaptive fashion
4. Social, economic, and environmental impacts are connected in a complex system. Impact pathways need to be articulated and second and higher order, wider impacts, considered.
5. Evaluation is a key component so that future analyses can learn from the results of past activities. The approach is therefore reflexive, evaluative and continually developing.
6. SIA can be prospective and retrospective. For example, the social impacts of unplanned events could be analysed retrospectively.
7. Participatory processes and local knowledge should be used to analyse concerns of those affected and use stakeholder knowledge in the assessment of impacts, appraisal of alternatives and monitoring and evaluation processes

Figure 1 Principles of Social Impact Assessment based on Vanclay (2003)

Figure 2 Typical process for Social and Distributional Impact Assessment

Stage 4 is the assessment of distributional impacts and understanding how transport policies and interventions impact different groups, including through participatory decision making processes which are a key component of social impact assessment (Vanclay, 2003). Distributional analyses consider how impacts (benefits and burdens) of transport systems are distributed among the population and whether there are inequalities among different groups of people or places. Assessments in practice and research have tended to focus on deprivation or low incomes, but also include: indigenous groups, gender, age, ethnicity, geographic location, household structure (e.g., children / single parents), household tenure, deprivation, car ownership, disability, faith, economic activity, educational qualifications, being in receipt of state benefits and indices of multiple deprivation (Lucas and Jones, 2012).

The English transport appraisal guidance (WebTAG) includes a distributional impact assessment of: user benefits; noise; air quality; accidents; severance; security; accessibility and personal affordability. Each of the social impacts noted above are rated on a 7 point scale for equity (DfT, 2015). French guidance suggests an equity index and mapping analyses and Sweden has guidelines for measuring gender equality in local transport (Anciaes and Jones, 2020).

Equality Impact Assessments (EqIAs) are frequently used as a tool by public bodies in the UK to screen, assess and monitor equality impacts, with some public bodies choosing to integrate an assessment of human rights implications into the same tool. An EqIA can provide an assessment of how transport interventions could potentially result in disproportionate or differential effects on the above protected characteristic groups. A group may be disproportionately affected by an identified impact as a consequence of a higher than average proportion of that group residing in an area. For example, severance of community in an area with a higher than average older population. A group also would be disproportionately affected should evidence show that their protected characteristic result in them being more vulnerable to the impact. For example, research shows that children are more susceptible to changes in noise level and air quality than other age groups. In other words, the uneven social outcomes as well as uneven distribution of transport related resources are important.

Scotland's Transport Appraisal Guidance (STAG) specifically advises on using the outputs of an EqIA to support the appraisal of accessibility and social inclusion impacts of transport project or policy (Transport Scotland, 2014). Furthermore, the Scottish Government are also undertaking Children's Rights and Wellbeing impact assessments on transport laws, policies and measures in line with the Children and Young People (Scotland) Act 2014. In addition to the protected characteristics groups included in the Equality Act 2010, the Fairer Scotland Duty also places a legal responsibility on particular public bodies in Scotland to pay due regard to actively consider how they can reduce inequalities of outcome, caused by socio-economic disadvantage, when making strategic decisions. Island Communities impact assessments are currently being developed to ensure that the interests of island communities are being considered as included under the Island (Scotland) Act 2018.

Stage 5 includes the development of actions for removing or minimising the negative impacts identified in assessment as well as enhancements for increasing beneficial outcomes. The actions could be wide ranging and include policy changes, partnership working with transport and non-transport service providers, environmental and construction processes and financial compensation.

Finally, **Stage 6** should involve the creation of a program to monitor impacts and the implementation of action plans, including assessment of social and distributional impacts. Evaluations should identify any further issues and inform future policy development.

Case Study: Highways England Approach to Assessing Equality Impacts of New Major Highway Schemes

Highways England (HE) is the governing organisation for England's strategic road network comprising of motorway and major highways or 'A' roads. It is responsible for the maintenance, operation and improvement of the national highways network totaling around 4300 miles (6920 km). Its aim is to ensure the road network is free flowing, safe, accessible and integrated whilst supporting the economy and resulting in long-term sustainable benefit to the environment (Highways England, 2015). It is also responsible for developing new major road schemes and seeking relevant planning consent from the UK Government for the implementation of these schemes.

HE produces EqIAs across a range of its policies and practices including the development of new major schemes as evidence of paying due regard to the Public Sector Equality Duty (PSED), despite EqIA not being a compulsory part of the transport appraisal process. As well as identifying impacts of proposed schemes on the groups with protected characteristics included within the Equality Act 2010 it also considers vulnerable and non-motorised users of the highway network, including pedestrians, cyclists, motorcyclists and equestrians. HE has developed the Equality, Diversity and Inclusion tool (EDIT) specifically to support the EqIA process for major highways schemes. The EDIT is a two-stage process designed to be used for assessing equality impacts of new major highways schemes. Stage one comprises an initial screening of potential equality impacts to determine whether a full EqIA is required. The screening process first identifies the following within an area of interest (typically one of the ten HE operating regions (UK Government, 2020)).

- the largest **numbers** of all people;
- the largest **numbers and proportions** of people from particular protected characteristic groups;
- destinations such as schools, hospitals, religious buildings and care homes; and
- concentrations of all of the above - people, equality groups and destinations.

The screening process also requires the user to determine whether a proposed scheme is likely to result in changes to the existing transport network, such as:

- pedestrian or community severance,
- access to public or community facilities or employment opportunities,
- Public transport usage or access,
- the streetscape and the pedestrian environment,
- Crossings on the highway network
- Physical accessibility; and
- Highway user experience.

Construction impacts such as temporary changes to the highway or footways, diversions and changes to routes, noise, dust and light environmental impacts, temporary construction employment and changes in access to facilities and services are also considered at this stage. Following the input of this information into the tool, an EDIT 'score' is provided and an initial EqIA screening is prepared. The tool provides a recommendation to proceed to Stage 2 of EDIT and a full EqIA as appropriate is based on the score and screening outcome.

Stage 2 of the EDIT tool captures further scheme design details including the main beneficiaries of the scheme, type of location (i. e., urban/rural) and potential impacts on nonmotorised users. Additional evidence obtained through other impact assessments (e. g., environmental impact assessments, WebTAG social and distributional impact assessments, health impact assessments and economic appraisal reports) is used to provide further information on potential adverse and beneficial effects.

The impacts of the construction phase of the scheme are also taken into consideration with regard to the environmental, health and accessibility impacts on the population. Social value outcomes associated with forecast job creation and skills legacy also forms part of the information input into the tool.

The EqIA draws upon the information gathered for EDIT to identify disproportionate and differential effects of identified potential impacts across protected characteristic groups. It also assesses feedback from public consultation and engagement with key groups as well as providing a two way input into the communication plan for the project by ensuring that consultation and engagement activities are fully inclusive.

Following the completion of the EqIA, action plans are developed and may include proposed design or policy changes and appropriate mitigation measures as well as programmes to monitor impacts over time. The EqIA and EDIT are considered to be 'live' documents recording and monitoring identified impacts and outcomes of are mitigation measured as a project progresses through different stages of development.

Practical Challenges and Guidance

The challenges to undertaking social and distributional impact assessments of transport policy and interventions are wide ranging. For the purpose of this article they are summarised under the following themes:

- Limitations of existing transport appraisal frameworks;
- Evidence, evaluation and monitoring;

- Spatial and temporal coverage of assessment; and
- Engagement and expertise.

Limitations of Existing Assessment Frameworks

As outlined in this article, there are a number of approaches to incorporating social and distributional impacts assessment in transport policy and project appraisal. However, these tend to be subsidiary, rather than driving processes. It is therefore unclear to what extent such assessments influence decisions or improve outcomes (Hickman, 2019). Relatedly, social impacts tend to be framed as negative side-effects of proposed transport policies or interventions, which need to be mitigated. Transport policy, however can help achieve social, sustainability and equity goals, if social impacts are considered from the outset.

Existing assessment frameworks have been critiqued for not keeping up with shifting policy paradigms and modern transport planning, which requires greater attention be paid to developing healthy, equitable and sustainable transport systems (Anciaes and Jones, 2020). Hickman (2019) suggested a mismatch between the social factors included in UK transport appraisal (accidents, physical activity and journey quality) and Sustainable Development Indicators (social capital, social mobility, life expectancy and housing provision).

Cost-benefit analyses are necessarily partial (Hickman, 2019) and while important social impacts may be noted they are often disregarded as unmeasurable (Anciaes and Jones, 2020) and excluded from appraisals (Searle and Legacy, 2019). Omitting social impacts can undermine the investment decisions by failing to account for the full range of impacts of a proposal (Searle and Legacy, 2019). The prioritisation of monetisable impacts, in particular journey time savings, can lead to investment decisions which prioritise road building and reduce the potential of transport investment to contribute to broader social policy and sustainability goals (Hickman, 2019). Considering how major projects perform in terms of meeting budget and time targets rather than improving communities can lead to negative outcomes such as community segregation (Mottee et al., 2020). Reliance on technical assessments and “objective” calculations means that cost benefit analyses are not seen as suitable for addressing issues related to social exclusion (Thomopoulos et al., 2009).

Cost benefit analyses are based on utilitarian principles of justice which seek to maximise aggregate welfare and do not consider the gains or losses of different groups (Thomopoulos et al., 2009). Searle and Legacy (2019) compare equity and social impacts to species extinction in that they are impossible to monetise in transport planning appraisal. Greater attention needs to be paid to aligning proposed policies or interventions with wider strategic objectives, even where impacts cannot be quantified (Hickman, 2019).

Evidence, Evaluation, and Monitoring

Social Impact Assessment is reflexive and evaluative (Vanclay, 2003) which means there is a need for good evaluation evidence to inform future practice. The difficulty in quantifying and monetising some social and equity impacts demands a stronger evidence base on the actual impacts of transport policies and interventions, to support analyses. Social impacts are part of a complex system, and understanding and articulating impact pathways, feedback loops and wider impacts, and changes in places and populations, beyond what can be accounted for in direct causal models is an important, yet challenging, part of the process (Anciaes and Jones, 2020; Vanclay, 2003). The long-term impacts and complex pathways to outcomes makes it harder to attribute social impacts to policies and interventions.

In practice, there has been limited evaluation and monitoring of transport interventions with regard to social impacts. Many evaluation frameworks are based on quantitative data collection to measure key performance indicators that can be directly attributed to interventions.

The literature focuses on three main types of transport related inequalities: transport related resources (car ownership/proximity to infrastructure); observed daily travel behavior (trip frequency/distances/travel time) and transport accessibility levels (Pereira et al., 2017). Social and equity impact assessments dominated by spatial analyses tend to assume that everyone in a particular place is impacted in the same way. However, health outcomes and inequities arising as a result of transport inequities feature less (Hosking et al., 2019). There is a need for a better understanding of differential outcomes. It may be that transport policies and interventions do not result in transport related inequities but do lead to inequitable outcomes in terms of health outcomes because people are impacted differently. There has been an increase in the use of epidemiological methods to understand the impacts of place based, built environment and infrastructure interventions on active travel. However, these have rarely focused on subgroup or equity analyses (Hosking et al., 2019).

Spatial and Temporal Coverage for Assessment

Assessments are often limited to the population in a given geographical area but impacts can be much wider, especially over longer timescales. Similarly, consideration needs to be made as to whether social impacts would be limited to the resident population of a given study area or those working in or visiting an area. Often, a detailed demographic breakdown is only available for the resident population. Census area boundaries may also provide an arbitrary boundary with limited relevance to the potential geographical impacts of a transport intervention.

Furthermore, most traditional demographic datasets provide only a static snapshot of the resident population, making it harder to assess the wider spatio-temporal travel patterns and needs of the population. The use of census and other secondary datasets can

also result in the risk of using obsolete data resulting in the omission of minority or underrepresented groups, for example where new communities have recently moved into an area.

Limited research has considered the uneven mobility offered by the public and active transport system at different times of day and the differentiated impacts based on gender, income and race (Smeds et al., 2020). Gaps in transport provision at night are particularly likely to impact low-income shift workers for example (Chandra et al., 2017). In addition to differential service availability at night time low income groups and women have been identified in the literature as facing fear-based exclusion at night time (Smeds et al., 2020).

Engagement and Expertise

Quantitative data alone does not provide a nuanced understanding of social issues and challenges affecting a community. Introducing new transport policies, plans and projects to an area without community engagement could lead to further exacerbation of transport issues and inequality. Engagement with local communities can be used to fill data gaps and gain a deeper understanding of existing issues. Standard consultation approaches are often perceived to take place once a decision has already been made, to inform rather than engage with the community. However, existing consultation processes often fail to include underrepresented groups, many of which are most vulnerable to negative social impacts leading to further potential social exclusion. There is also a need to recognise and value different types of evidence, including community experiences and understandings, and expert evaluations. Understanding social impacts is not a purely technical exercise but requires meaningful community engagement and social science expertise (Hickman, 2019). Failure to engage with social scientists results in overly technical, apparently objective assessments of social impacts, seen as a tick box exercise, which is not well suited to understanding complex social processes.

Conclusions

Assessing the social and distributional impacts of proposed transport policies and interventions is crucial to promoting healthy sustainable and equitable transport systems. Traditional transport planning appraisal systems have not adapted well to changing transport planning paradigms which require a focus on the ways in which transport systems contribute to quality of life, not just the efficiency of the system. Transport systems can contribute positively to social, equity and environmental objectives meaning that consideration of social impacts needs to take place at all stages of the policy process, and not simply be seen as a mitigation exercise and the option appraisal stage, as often is the case.

Approaches to assessing social and distributional impacts are often moulded to fit existing technical approaches. However, the political nature of decision making in transport needs more explicit consideration (Mattioli et al., 2020). A technical assessment may draw attention to differential impacts, but whether or not such distribution is fair is a political and ethical decision. A focus on equity should also take into account whether the systems and decision-making processes are fair. It may be that inequalities in transport can be considered fair, and in some cases necessary to achieve equitable outcomes, provided everyone has good levels of accessibility to essential services. Jones and Lucas (2012) recommend use of minimum standards of transport provision, equity and fairness. Ensuring that transport policies and interventions meet agreed minimum standards and maximum harms could help address some of the challenges of detailed social and distributional impact assessments outlined in this article. More fundamentally, it is important to remove systematic marginalisation and discrimination, and unfair differences in outcomes or exposures.

Introduction

Building healthier cities has been a core objective of state planning since Victorian times. With time, and with the entrance of a variety of actors and interests in shaping planning, this holistic principle has been over-ridden by other focuses. The attention has shifted from planning as a state-directed process to implement a clear societal objective (health, justice), to the means and processes to potentially achieve those, with increasing attention given to ideas of growth or innovation (Barton et al., 2015; Ferreira et al., 2020).

The COVID-19 pandemic has demonstrated how this can be quickly reverted, with public health becoming an incredibly powerful reason for implementing radical and rapid changes in our urban environments. This experience, combined with increasing awareness in the public domain of the damaging health effects of past planning choices, can support the implementation of key shifts also in the way transport systems are planned. Transport plays in fact a key role both in the reproduction of damaging health impacts and in the development of new urban environments in which health is at the centre.

This article explores how transport planning can contribute to improving human health and wellbeing. It will explore the negative health outcomes linked to oil-based and motorized transport systems to then discuss and consider the way transport and mobility can be linked to societal wellbeing. Subsequently, potential policy approaches to plan mobility for healthy cities, considering both their advantages and limitations, will be considered. In this, an analysis will be developed to consider the political aspects of transport and mobility planning, highlighting the importance of an approach that considers issues of power and economy and that gives voice to different planning actors, including citizens.

How Current Transport Systems Affect Public Health

There is nowadays substantive evidence of the negative impacts that transport can have on public health. These negative impacts are mainly linked to the widespread use of motorized and oil-based transport modes, especially the private car (and, increasingly, the airplane). Car dependency produces negative health impacts both directly, affecting individual health, and, indirectly, determining changes in behaviors and the environment (Khreis et al., 2016).

In the first place, transport systems designed around the private car, with their high consumption of public space and high speeds, are substantially responsible for an enormous number of deaths worldwide, which has been globally accepted in a “rather unquestioning manner” (Wells and Beynon, 2011, p. 2494). The WHO (2018) reports that approximately 1.35 million people die each year worldwide as a result of road traffic crashes, with road traffic being the leading cause of death for people aged 5–29. These crashes affect disproportionately noncar users, showing that fundamental justice issues permeate the way pedestrians and cyclists suffer the most from someone else’s use of a motor vehicle (Culver, 2018). Research has shown how this effect is sharpened in areas of higher deprivation or in poorer countries where traffic incidents’ victims are often young adults from less wealthy groups (Culver, 2018; Wells and Beynon, 2011).

Secondly, the high number of road vehicles generates substantial changes to the environment, which impact human health. Air pollution is recognized to be main cause of vast negative health effects such as cardio-vascular, cerebral-vascular and respiratory mortality and morbidity, decreased lung function in children, diabetes and, recently, coronavirus fatalities. Motorized transport constitutes a key cause of urban air pollution: nitrogen oxides, carbon monoxide, and volatile organic compounds are released in great quantities both via exhaust emissions, whilst particulate matter is released as a consequence of wear and tear phenomena (e.g., tyres and brakes) (Khreis et al., 2016). Air pollution, similarly to what happens for traffic incidents, is also disproportionately felt by minorities and vulnerable groups across cities worldwide. For example, research has shown that in the USA Black and Hispanic Americans are disproportionately affected by air pollution mostly produced by white Americans consumption (Tessum et al., 2019). Similarly, in the UK, low-income households have the highest levels of exposure (Barnes et al., 2019).

Together with augmenting air pollution, motorized transport is responsible for other changes to the environment that is detrimental to human health. High noise levels, local temperature raises, reduction of green space, and biodiversity loss have vast and lasting effects on physical and mental health, negatively impacting human life worldwide (Khreis et al., 2016). At the same time, motorized transport is the second largest and still growing contributor to global greenhouse gas emissions and especially carbon dioxide (CO₂), the backbone of climate change, and therefore is directly responsible for warmer weather and extreme weather events (Chapman, 2007). Those are reported to have substantial health impacts for all and especially most vulnerable and less mobile individuals. Climate change is likely to increase thermal-related mortality, water/food/vector-borne diseases, skin cancers, malnutrition, respiratory diseases linked to augmented air pollution, as well as direct increase in injury, and deaths as effect of extreme climate events (Nichols et al., 2009). Moreover, extreme climate event, as well as long-term environmental changes such as droughts, will generate important mental health effects, damage livelihoods of already vulnerable population with resulting lack of access to land or clean water, forced mass migrations, and broadening of societal inequalities (UNDP, 2007).

Finally, a transport system relying primarily on motorized transport promotes a sedentary lifestyle which is also a main causes of cardiovascular diseases, cerebrovascular disease, cancer (colon, breast, and lung), type 2 diabetes, dementia, anxiety, depression, obesity (Khreis et al., 2016). A less car-centered transport could instead promote the adoption of active forms of transport that can answer to the damaging health impacts of sedentary lifestyle. Research is increasingly showing how the benefits of active travel are at least one order of magnitude greater than the damages suffered from air pollution, so even cycling in much polluted cities will provide important health benefits! (Tainio et al., 2016).

How Current Transport Systems Affect Human Wellbeing

Together with directly impacting individual health, motorized transport affects other aspects of human life that are core to achieving wellbeing for all. These become especially evident when we adopt a definition of wellbeing which links to the Aristotelian tradition of wellbeing as “eudamonia”, that is the realization of one’s true potential and autonomy.

Transport has a direct responsibility in allowing people to access jobs, education, health, social networks, and the concept of accessibility has become key in a wide range of studies in transport geography (Litman, 2007). At the same time, the way we are able to travel or move and the way we experience it—trapped in a crammed bus in a very hot day, or smoothly driving our car on a quiet road—shapes our mood (Avila-Palencia et al., 2018), and also the meaning we give to places, our identity, and social relations (Doody, 2020). Transport affects also wellbeing at a more-than-individual level; there are strong interlinks between each individuals’ mobility practices and the fact that movements and the possibility for movements are collectively determined, both as a mother drives her kids to school or as a bus stops the flow of car traffic, or a ban on informal transport hinders access to livelihood for a working parent. A malfunctioning transport system, which might force some groups to rely on very low quality and unsafe transport means, or even not have access to any, can generate key societal inequalities and crucially impact the wellbeing of wide groups of the population. Malfunctioning transport systems are linked to phenomena of community severance, loss of social network, and most importantly, social exclusion and poverty.

Transport and mobility scholars have been examining these links and have highlighted how, in a system designed around the private car, uneven access to it, often or coupled with very limited availability of alternatives (both because of affordability and reach of services) generates phenomena of “transport poverty”, which includes issues related to lack of mobility, accessibility, and affordability of transport (Lucas et al., 2016). Transport poverty, which results in forced immobility or high part of one’s income spent to allow mobility, heavily impacts people’s ability to live a fulfilling and meaningful life. Research has shown also that such effects are particularly felt by those groups who are already disproportionately impacted by transport-related air pollution, even though they emit the least (Jephcote et al., 2016). The effects of motorized transport are in fact strongly unequally distributed with relation to income, gender, race, age, sexual orientation, and their intersection, and, as highlighted in relation to climate change effects, are strongly impacting poorer populations in nonwestern countries.

Planning Transport: a Policy Approach to a Complex Problem

Popular substantial pathways to tackle these impacts are suggested in terms of both *technological improvements* (adoption of greener technologies for motorized transports which reduce air pollution and adoption of smart technologies to increase traffic safety), *modal shifts* with promotion of active travel to solve both air pollution issues and damages linked to sedentary lifestyles, *land use changes and other urban policy measures* which would reduce number of trips and cars, need for travel, and would allow more green space or walkable environments (see more in Nieuwenhuijsen, 2020).

In support, further actions are now being coordinated across academia and the policy realm, often promoted by the WHO, with the aim to, for example, develop strategies to promote transport safety reducing car accidents and enforcing safety standards (World Health Organization, 2017b), fully assess health impacts of different transport interventions (World Health Organization, 2017a), and increase awareness of the links between transport-related air pollution and climate change effects. All these efforts recognize that addressing the complicated links between transport and health is a complex matter which requires coordination at different levels (Nieuwenhuijsen, 2020).

Firstly, transport planning is a complex subject which intersects with several domains of research and knowledge. Although traditionally addressed as part of an engineering problem, and lately within frameworks of classical economics, it is increasingly evident that *interdisciplinary efforts* are required to understand what transport and mobilities are about, their links to wellbeing, and which directions of change are possible. Increasingly, methodologies and theories from epidemiology, health science, social science, anthropology, geography, but also artificial intelligence, psychology, have been able to create a more adequate understanding of transport systems, in their being an intricate “ensembles of infrastructures, technologies, practices, regulation, meanings, values, affects enabling, and shaping the (non)movements through physical space of people, goods, and waste” (Schwanen, 2019, np). Amongst other results of these efforts, it is worth highlighting the development of sophisticated forms of Health Impact Assessment (often including participatory aspects) that are able to provide a strong narrative for policy makers evaluating alternative options for future transport scenarios (Nieuwenhuijsen et al., 2017).

Secondly, given that transport crosses several aspects of planning and policy, *integration at different levels of policy making* is a crucial requirement to be able to implement meaningful changes. In this regard, cities are increasingly becoming protagonists in coordinating efforts at different levels of local governance, for example by adopting Sustainable Urban Mobility Plans, or coordinating at a regional, national and international scale with new emerging networks and exchange exercises such as the World Health Organization’s (WHO) Healthy Cities. They have also opened substantially to the intervention of other actors, from universities and NGOs, to partnerships with private stakeholders and consultants to design different solutions. They have supported the emergence of Urban Living Labs as experiments of different forms of mobility (Voytenko et al., 2016), or adopted new forms of governance embracing the idea of transition management (Loorbach, 2010).

Thirdly, there is a growing awareness of the importance of *integrating health objective with sustainability objective*. Efforts towards improving the uptake of active travel or reducing overall the need for travel are crucial in this sense. Similarly, technologies which increase engine efficiency, or which allow citizens to approach “Mobility as a Service” can be of key importance. Amongst others, the WHO THE-PEP (WHO Transport, Health and Environment Pan European Programme) include important guidelines for working to integrate transport planning with health and environment.

These strategies, often combined, are allowing several (Western!) cities to start adopting healthier transport solutions, reducing carbon emission and fuelling the adoption of active travels. Key recent examples include Barcelona, with the innovative idea of superblocks, localized pedestrian areas at the level of a street block (Rueda, 2018), Paris, which has adopted the idea of a 15 min cities, boosting the adoption of walking and cycling, and Milan, equally promoting an idea of a polycentric and hierarchical transport system, especially in response to COVID-19 (Pisano, 2020).

However, there are still broad questions linked to the possibility of these strategies to last and to be implemented in other geographies. Most importantly, attention should be paid also to the shortcomings of certain planning and policy choices, especially if we adopt wellbeing and not a restricted idea of health as “being free from harm” as a definition of the final aim of planning.

A Matter of Politics and Power

The aforementioned pathways to implement change come with a series of shortcomings.

First, a pure focus on *infrastructural and technological change* is unable to provide the required change and transport planning too often seems to remain trapped in a fascination with innovation. As analyzed by Reigner and Brenac (2019), for example, the current emphasis on automation as a panacea to traffic incidents is showing to be distracting planners from other most suitable options, such as investing in public transportation or active mobility. A focus on automated driving is pushing forward a narrow conception of health as simply “being free from harm” and therefore missing the option of reforming transport systems via also improving urban environments, social life (e.g., by in promoting cycling or walking, or land use changes) and therefore wellbeing. Similarly, limitations are also linked to an obsession with *mode change* that does not account for the problematic nature of considering modal choices as a purely individual and rational decision (Ferreira et al., 2020), and promotes instead paternalistic solutions aimed at “educating citizens”. As stressed also by Reigner and Brenac (2019), the “individualization” of health, both in terms of who is responsible for it—the single rational individual—and at which level of intervention health issues ought to be solved—by primarily modifying individual behaviors and choices—is effectively missing to account for the interconnected nature of mobilities and wellbeing. For example, road accidents are often considered being consequence of individual misbehavior, whilst instead research is increasingly showing that they are most likely linked to the way the transport system itself is designed.

Second, a *holistic and interdisciplinary* approach to transport planning is often hindered by issues of translation between different disciplinary silos, which have their own specific understanding of which knowledge and language is more authoritative. This is evident in the tendency to prioritize quantitative methods and accounts over more qualitative methodologies, although the latter have demonstrated to contribute substantially to widen the understanding of the relationship between transport and wellbeing. Although there is a call for breaking these silos, obstacles remain given the issues with translation between departments and people embedded in different disciplinary traditions. Moreover, there are key issues in translating academic knowledge into a language and format accessible to policy makers. These obstacles further hinder the creation of a holistic way of transforming transport systems and are particularly challenging to address given also the unequal distribution of centers of knowledge production around transport which prioritizes knowledge coming from Western, English speaking countries.

Third, there are issues linked to the “*one size fits all*” idea which often is embedded in knowledge-exchange exercises, such as the international frameworks mentioned earlier, or promoted by consultants who are increasingly popular in transport planning.

Implementing effectively “best practices” ideas imported from other places and contexts reveals to be most of the times highly problematic. For example, authors have shown how even extremely flexible frameworks such as the idea of Bus Rapid Transit, promoted strongly by the World Bank to solve transport issues in developing countries, can create great issues when moved from one context to the other. A project that does not acknowledge the intricate local political economy of other transport and mobility systems in place can fail both in terms of meeting the needs of local populations or in being correctly implemented (Rizzo, 2015). Similar issues can also emerge when trying to pedestrianize a local area without accounting for the time that a specific change in land use might take or broader political conflicts around local authority (as happened e.g., also in the superblock case of Barcelona, see Scudellari et al., 2019).

Fourth, even when success stories are presented, there is a key duty in trying to understand *by whom* these stories are told and *who* is effectively benefitting from the success. In the complex world of contemporary cities, policies and transformations would always be contested and controversial and, sadly, most of the time benefits who is already better off. Even designing and implementing interventions able to truly respond to both the need to reduce carbon emissions and, at the same time, care for everyone’s health and wellbeing can pose several challenges especially in terms of equity. For example, amongst several issues that planners ought to consider is the phenomena called “green gentrification”: the increasing costs of living (and moving to and from an area) and subsequent displacement of most vulnerable residents as consequence of greening policies and urban renewal, often including pedestrianizations, cycle lanes and new urban parks (Gould and Lewis, 2016). Equity analysis or, even more in depth, looking at whose capabilities and needs are enabled or hindered by new urban or transport policies, is therefore a duty to ensure that healthy cities are as such for all.

Overall, it is clear that far from being a technical exercise, transport planning is a highly political matter, with research increasingly demonstrating the importance of analyzing the role of different actors and powers in shaping the way choices are made and implemented. Above all, it is evident the predominance and persistence of the automobile in today’s transport systems is far from being merely a result of policy choices. As shown by Mattioli (2020) in a key paper recently published, the key role given to the automobile in western (and increasingly nonwestern) mobility systems is the result of a number of interests that different powerful actors have been able to impose on the local, regional, national, and global agenda. Changing this trend cannot be achieved just by coordinated policy efforts.

Planning in the Public Domain

In 1987, Friedmann published a key text in which the idea of what planning is was explored in detail. Although much time has passed, the book is still insightful. It proposes to consider planning as a process of translating knowledge into action in the public domain, which is not only enacted by policy makers, but performed as an activity in which different actors, actions, and epistemologies converge. In this way Friedman includes urban social movements and other grassroots actors in the definition of planning, recognizing that “oppositional movements are essential to a healthy society, [and] point to the possibility of a fuller humanity” (298).

As other authors have highlighted (see e.g., Schwanen and Nixon, 2020), opening up planning to more participatory forms of decision making and urban transformation is particularly important, especially when what we are looking for is the redefinition of the paradigm of transport planning away from an idea of speed and efficiency (or profit) and toward health and wellbeing. It is also crucial when we want to re-politicize the idea of planning and understand urban change as composed as a myriad of interests and needs who are often conflictual. This opening, however, is different from simply and uncritically opening up the “public domain” to private actors and stakeholders who might push for shaping urban development in favor of specific economic interests (as often is the case with the increasing popular use of Public Private Partnerships which often results in privatization of public assets (Mirafteb, 2004)).

Opening up planning to participatory forms of decision making is a process through which actors such as local residents, citizen groups and especially vulnerable or hard to reach groups can have a voice in shaping voicing their needs and linking them to the direction of urban development. This can be done by complementing usual planning methods with more in depth connections with the lives and stories of who would be impacted by these changes, for example, via using ethnography, diaries, open meetings, and narrations. These data and opening can help tailoring responses to what is most appropriate to the content, in terms of what is culturally feasible, integrated with the local landscape and economies, and responding to the needs of the most vulnerable in the first place (see Fig. 1).

At the same time, such opening can be achieved by linking with the critical work of social movements that have historically reported, analyzed and helped tackling several issues in terms of urban equity and transport justice (Sheller, 2018). Amongst several other examples, it is of great inspiration the work of the Untokening, a USA “multiracial collective that centers they lived experiences of marginalized communities to address mobility justice and equity” (<http://www.untokening.org/summary>). By using critical race theory, the collective is helping planners rethinking the politics of public transport, walking and cycling, and building mobility justice. More simply, it is cycling activists that have played a crucial role in pushing the bike revolution in the Netherlands (Feddes, 2019) and that are now sustaining daily the implementation of Low Traffic Neighbors and walking and cycling environment in the UK, Europe, and elsewhere, often supporting in a unique manner the adoption of active travel in more disadvantaged areas (Schwanen and Nixon, 2020).

Conclusion

In this article, the links between transport planning, public health, and human wellbeing have been explored, highlighting the current efforts that policy makers, planners, and international institutions are promoting. The article has highlighted the potentials of an interdisciplinary, coordinated approach that contextualizes health in the broader picture of transport and climate change. At the same time, the limitations that these approaches might have when not accounting for the contested and political nature of transport planning are exposed. The proposal is made to open up further to a process of politicizing the debate including marginalized voices and grassroots actors in the planning sphere.

What is suggested is a very difficult journey that might need a shift in the way resources for planning are considered and distributed, combining the reliance on fairly low-cost technologies and infrastructures (such as cycle ways and pedestrianizations) with more resources invested for public engagement and interdisciplinary conversations. Most importantly, intellectual resources should be invested in shifting the paradigm of planning toward opening up to new voices and discussion, destabilizing the predominance of the idea of speed and efficiency (and profit) as drivers of urban development and promoting planning as a complex, interdisciplinary, adaptive and multiscale and dynamic search for localized, and nonnormative solutions to local needs.

Introduction

Transport Demand Management (TDM) has traditionally comprised all mobility strategies with the aim to reduce private car use and promote public transport in big cities. The effectiveness of TDM strategies concerned the improvement of environmental and sustainable levels of the entire transport system. During the last decades, political pressure to improve air quality indicators in cities has increased and added more to the value of TDM strategies. The United Nations emphasized this issue in 2016, when more than 91% of urban dwellers were breathing unsafe air, with the result of 4.2 million deaths reported to be related to ambient air pollution (United Nations, 2018). Additionally, more than half of the global urban population is exposed to air pollution levels at least 2.5 times higher than the safety standards, with transport pollution being a major contributor to these figures (United Nations, 2018).

The resolution adopted by the United Nations General Assembly on 25 September 2015 defined the 2030 Agenda for Sustainable Development and one of the goals, the 11th Sustainable Development Goal was directly related to making cities and human settlements inclusive, safe, resilient, and sustainable (United Nations, 2015). The role of TDM strategies to achieve the 11th goal commands greater importance, and demands effective and quick solutions. Reduction of air pollution and consumption of fuel are not only the main objectives of new TDM strategies but also the reduction of noise and vibration, as well as accidents or community severance. Fortunately, new ICTs, the wide spread of smartphone usage, the innovation in vehicle manufacturing (electric and autonomous) and the emergence of the sharing economy offer a wide variety of opportunities to design new TDM strategies which up to now were unthinkable.

This chapter's contribution lies not only in describing the origin and evolution of Transport Demand Management but also in the proposal of a new TDM approach based on the technological change of the urban and interurban transport environment.

The Origin and Evolution of Transport Demand Management (TDM)

The origin of Transport Demand Management (TDM), also called "Mobility Management," took place at the end of last century (Nijkamp et al., 1998; Banister, 1999), when the absolute growth in travel, especially by car and plane, started to create a serious concern in terms of pollution (emission of harmful gases). At the urban level, reducing private car travel became the main objective of the first TDM strategies. Specifically, the target was the reduction in vehicle kilometers from trips made by environmentally damaging modes of transport, like the private car. At European level, transport policy programs reflected this concern on the increase of private car traffic (CEC, 1992, 1993). The electric car market had not yet taken off and smart technologies were not so powerful to connect transport users to operators, and other users. The context in which Transport Demand Management originated should not limit the concept of TDM to the strategies of solely reducing private car travel. TDM should be defined as the **design of a group of strategies devoted to improve the efficiency of the transport system exploring demand side measures**. The key issue is what we understand by "efficiency of the transport system" at any time in history.

Marshall and Banister (2000) were the first to understand the complexity of exploring only demand side measures when designing TDM strategies to reduce private car travel in cities. In order to reduce private car travel, an alternative of transport should be provided to private car users (like mode substitution or modal shift to public transport). Even decreasing the distance traveled by private car requires the adoption of other complex policy measures linked to the labor market (such as, the implementation of teleworking) and the change of location of activity centers in cities. Direct **push measures** (i.e., tax increase on fossil fuel) should be combined with **pull measures** (i.e., improvement of public transport or ticket price reduction) to achieve larger behavioral responses compared to the individual push measures. Marshall and Banister (2000) proposed the design of "strategic packages" to ensure that combining push and pull measures can achieve a tangible reduction in travel.

Some years later, Litman (2003) collected an "Online TDM Encyclopedia" showcasing 48 TDM strategies implemented all over the world, including push measures (measures to directly reduce private car use) and pull measures (to indirectly reduce private car

Table 1 Short- term TDM strategies included in the online TDM encyclopedia

<i>Incentives to shift mode</i>	<i>Improved transport options</i>
Bicycle and pedestrian encouragement	Address security concerns
Congestion pricing	Alternative work schedules
Distance-based pricing	Bicycle improvements
Commuter financial incentives	Bike/transit integration
Fuel tax increases	Carsharing
High occupant vehicle (HOV) priority	Guaranteed ride home
Pay-as-you-drive insurance	Park and ride
Parking pricing	Pedestrian improvements
Road pricing	Ridesharing
Vehicle use restrictions	Shuttle services
	Taxi service improvements
	Telework
	Traffic calming
	Transit improvements universal design

use). Following the approach of [Marshall and Banister \(2000\)](#), [Litman \(2003\)](#) emphasized the integrated vision of TDM planning, providing information on how various specific strategies can be combined for maximum effectiveness. Indeed, one of the major contributions of Litman was the identification of 48 different strategies already implemented, a very complete inventory of TDM actions, that provides the profile of the TDM type implemented at the end of the 20th century. [Table 1](#) and [Table 2](#) show the inventory of actions identified by Litman. [Table 1](#) groups short-term actions directly linked to the most common push and pull measures related to the reduction of private car travel, and [Table 2](#) shows more general long-term measures linked to land use management and policy reforms.

Each TDM strategy was defined by a combination of possible actions and registered with a short description and a list of indicators: how it was implemented, travel impacts, costs and benefits, equity impacts, application, relationship with other TDM strategies, stakeholders, barriers to implementation, best practices, case studies, references, and resources for more information.

The inclusion of equity impacts to the description of the TDM measures ([Litman, 2003](#)) reflects the start of a growing concern about the social fairness of transport policy measures ([Martens, 2016](#)). TDM can push users with lower incomes with less accessibility from their homes to key destinations (e.g., labor destinations) to reduce driving and shift to public transport modes. Fair transport accessibility is a key issue to achieve social equity in transport and a minimum standard of accessibility to the main destinations is required to respect individuals' rights and protect disadvantaged groups. According to [Lucas et al. \(2015\)](#), methodologies to assess new transport policies should include theories of *egalitarianism* and *sufficientarianism* in combination with an accessibility-based analysis using the Lorenz curve and Gini index. Accessibility studies need more research and a more complete understanding than traditional approaches to incorporate the concepts of equity and justice in transport. This indeed was the development trajectory for the evolution of TDM and its assessment.

Each TDM listed by [Litman \(2003\)](#) was also rated on a seven-point scale, including criteria related to their travel impacts and their ability to achieve some objectives. The range of possible objectives defined by [Litman \(2003\)](#) shows, in some way, the range of criteria of TDM efficiency used until 2003. TDM was defined, at the beginning of this chapter, as a group of strategies devoted to

Table 2 Long- term TDM strategies included in the online TDM encyclopedia

<i>Land use management</i>	<i>Policy and planning reforms</i>	<i>Implementation of support programs</i>
Car-free districts	Car-free planning	Access management
Clustered land use	Comprehensive transportation market reform	Campus transportation management
Location efficient development	Institutional reforms	Data collection and surveys
New urbanism	Least cost planning	Commute trip reduction
Parking management	Regulatory reform	Intelligent transportation systems
Smart growth		Freight transportation management
Transit oriented development (TOD)		School trip management
Street reclaiming		Special event management
		TDM marketing
		TDM programs
		Tourist transport management

improve the efficiency of the transport system exploring demand side measures. The list of efficiency criteria includes not only congestion reduction or transport choice, but also road and parking savings, consumer savings, road safety, environmental protection, efficient land use and community livability. Environmental protection has also gained importance among the evaluation criteria over the years. Some authors have underlined that effectiveness of transport policies concerns directly the improvement of the environmental performance of the transport system (Vieira et al., 2007). The recent UN Sustainable Development Goals (United Nations, 2015) further support this approach.

In 2016, Ison and Rye (2016) proposed an alternative classification of TDM measures aimed at influencing people travel behavior. They divided TDM actions into economic measures, land use measures and administrative measures, but introducing new typologies of actions as those based on “information for travelers” (travel information before a trip is undertaken or carsharing) or “substitution of communications for travel” (such as tele-working and e-shopping). These new types of TDM reflect the new trends of mobility which started to emerge in 2016.

The assessment of TDM strategies, which have already been implemented is a complex issue. Accurate information on users' behavior changes is not easy to obtain and while information exists, it is scattered across different administrations and public access to this data is sometimes limited. In recent years new ICTs and internet-based information resources have been developed and information in support of TDM planning and evaluation has improved. Prior to the recent technological changes, three different types of studies (Eriksson et al., 2010) have been carried out to assess users' behavioral responses to TDM:

- Field experiments to measure cause-effect relationships (e.g., user surveys, traffic flow measured by road gauging stations)
- Estimation of transport elasticities, based mainly on stated preference studies
- Analysis of hypothetical TDM measures

Literature on field experiments shows that changes in the cost of transport (fuel cost, public transport tickets) definitely influences travel behavior (Heath and Gifford, 2002). Research on transport elasticities tries to design indicators to measure the extent to which travel demand is sensitive to changes on public transport services or private car pricing (push and pull TDM measures), looking for a ratio of the proportional change of behavior to the proportional change in services, fares or prices. According to some literature a 10% increase in fuel prices only generates between 1% and 3% car use reduction (Dargay, 2007), while improvements in public transport, such as a 10% service increase, provide a higher percentage of public transport ridership (5%) (Evans, 2004). The debate between the efficiency of push measures against pull measures has been very intense, but a general consensus on the need of mixed solutions as a package within the TDM strategy has been consistent over the years (Banister, 2008; Vieira et al., 2007). Although this scientific consensus is a good goal for the evolution of TDM, the emergence of the concept of “MaaS” will open a new scenario for debate in this area.

A Disruptive Tool for Transport Management: Mobility as a Service (MaaS)

During the last decade mobility has experienced several disruptive changes which greatly complicate the analysis of transport demand management measures. These include:

- Widespread use of ICTs among the population (particularly smartphones)
- Social acceptance and confidence in the new consumption forms brought forward by of the “sharing economy”
- Decisive progress in the development and implementation of autonomous vehicles
- Important advances in the development and implementation of electric and hybrid vehicles

Some of these disruptive changes are interdependent. For example, the acceptance of the sharing economy has been promoted by the mass use of smartphones among the population and the design of easy-to-use applications (apps) which need no specialized digital skills. Additionally, the implementation of autonomous vehicles assumes a continuous digital communication between users, road infrastructure and vehicle operators guaranteed by the mass use of ICTs.

In this context, the concept of MaaS has emerged turning the old TDM vision on its head. New technologies including autonomous vehicles and transport systems are being closely linked to a service concept, in a scenario where mobility is no longer consumed as a “good” (based on private vehicle ownership), but rather as availability to access the transport system. The majority of MaaS forms offer door-to-door multi-modal integrated mobility services, being an alternative to private vehicle ownership. MaaS is provided via digital platforms connecting users and service operators, so users have previously to be subscribed to smartphone applications designed by operators. There is no scientific consensus on the requirements of a service to be considered a MaaS form and how to compare different MaaS services. According to the literature (Pangbourne et al., 2020), this term was firstly used in a doctoral thesis read in Finland in 2014 and, some years later, a good inventory of MaaS definitions and concepts was also produced by Sochor et al. (2018), who analyzed the more frequent key words used to define MaaS: integration, multimodality, user-centric, on-demand, multimodality, flexible, platform, door-to-door, one-stop shop and seamless transport systems. One of the most completed definitions was provided by Arthur D. Little (2018), who considers MaaS an integrated, flexible and user-oriented mobility service developed through a digital platform (app), combining public and private transport providers. This platform should not only help to plan the trip but also to pay a true mobility package (a multimodal trip) covering the needs of each customer segment. Obviously the report by Arthur D. Little (2018) defined an advanced type of MaaS service, but Sochor et al. (2018) were

conscious that currently implemented MaaS does not achieve this advanced level of integration, and went on to identify four level of possible “integration” in order to classify the topology of each MaaS:

- Level 0. No integration (separate services)
- Level 1. Integration only of information (multimodal travel planner, price info)
- Level 2. Integration of booking and payment (single trip, find, book, and pay)
- Level 3. Integration of service offer (subscription, contacts)
- Level 4. Integration of societal goals (policy, social incentives)

The progressive implementation of MaaS has generated a debate within the scientific community on the threats that this new mobility approach can represent for transport equity and sustainability and which TDM strategies should be the more suitable within the context of this new development. As level 4 is rarely achieved, [Sochor et al. \(2018\)](#) raised their concern with respect to societal goals and highlighting the role of public administrations in particular. More recently, a number of authors have underlined the adverse effects that MaaS can generate if not organized properly ([Wong et al., 2020](#), [Pangbourne et al., 2020](#)). Based on flexible travel, modal integration and shared mobility, these new platforms will generate induced trips, potentially increasing congestion, and compromising road capacity. If modal efficiency is not achieved, sustainability problems will come back and, in the longer term, MaaS would also modify the urban structure, impacting the land use features in each territory. Indeed [Wong et al. \(2020\)](#) have been pioneers in considering the need for a type of MaaS based on a government-contracted model, with road pricing being incorporated as part of the package price, depending on the mode efficiency, time of day or land use characteristics.

Threats of the MaaS Model and Need of New TDM Strategies

In terms of the design of a new TDM strategy, the existence of MaaS systems should be incorporated as an additional variable in the urban scenario, not as a solution itself. The potential of introducing and increasing new road trips is one of the many threats associated with the implementation of MaaS platforms due to their increased levels of accessibility. Scientific evidence of this fact has been recently revealed in different studies that analyze the new forms of mobility that integrate MaaS and now are currently in operation (like Free Floating Car Sharing). Surveys on future travel behavior have also revealed that autonomous vehicles will induce further new road trips and in the long term, change the shape and structure of our cities.

Autonomous vehicles could increase the efficiency of TDM actions, in terms of traffic safety and management, but their only existence does not guarantee better TDM strategies. The main targets of the autonomous vehicle are improving traffic flows and increasing road safety. Autonomous vehicles will allow for narrowing of lane widths in streets, reducing distances between vehicles (headways) and removing traffic signaling at intersections; and in the long term, reducing the levels of investment in road infrastructure ([Talebpour and Mahmassani, 2016](#)). Extra-capacity of the road network is the first promise of the autonomous vehicle innovation and can be viewed as a panacea for their on-demand mobility potential. But due to the time savings, an induced demand is also expected not only from existing drivers (the time saved in travel will be invested on traveling further or developing more trips) but also from non-drivers. In this induced additional flows, operational trips (zero-occupancy vehicles to relocate vehicles or recharge electric batteries) should also be considered. [Harb et al. \(2018\)](#), showed some of the impacts that autonomous vehicles will have on people’s travel behavior with a 76% increase in km traveled, longer trips and more displacements in the evenings than previously. Considering all trips in the new system, 20% would carry no passengers.

The percentage of private ownership of autonomous vehicles is a key issue for the sustainability of the whole transport system. Even thinking on the hypothesis of a universal transport system based on “automated taxis” (robo-taxis or taxibots), all operated by a mobility provider ([Enoch, 2015](#)), TDM strategies have to be carefully designed to avoid urban sprawl and road congestion. Automated taxis would replace private cars (due to externalities), conventional taxi (due to the lower cost of automated taxis), and buses (due to their failure to satisfy point to point demand). Urban sprawl would be promoted by this new transport system and the threat of road congestion may also limit the number of trips per family/person and the mobility provider will have to restrict the individual freedom to travel. As an alternative, TESLA has proposed a scenario where autonomous vehicles are privately held but hired out, when not used, for ridesharing. This scenario improves some of Enoch’s scenario freedom limitations but the temporal efficiency will depend on the proportion of private vehicles over the total and the complex demand management of the whole system (spatial and temporal peak hours). All these first studies reveal the need of a comprehensive digital interconnectedness of all involved actors, not only all the modal operators but also public administrations and regulators. Indeed, new TDM strategies should be promoted on the basis of this new structure.

More evidence generated by new types of MaaS systems can be found in the new generation of carsharing: the so called FFCS (Free-floating carsharing). FFCS can be considered a type of MaaS with the topology of Level 0. There are platforms in cities that offer integration of travel information (Level 1), including all carsharing operators and it is possible to plan a multimodal trip, obtaining an estimation of the total price, but in the majority of them the booking and payment has been carried out through each FFCS company web. As level 4 is rarely achieved, these systems can also represent a threat for the transport system sustainability, and new TDM strategies should incorporate this approach. If new FFCS users are transferred from public transport, are displaced from active modes and increase the number of vehicle-km traveled, then the positive FFCS effects on the transport system should be questioned. Moreover, FFCS cars, even electric ones, occupy a space in the traffic flows, influencing the level of service of the road urban traffic

flows where public transport operates. It would be necessary to study if, in the majority of the FFCS displacements, trips are also shared or not (vehicles are occupied only by a sole driver with no passengers). Finally, FFCS cannot be conceived without the existence of an efficient public transport network that would guarantee a return or next trip should a car be unavailable at the time required and at the location of the user. There is indeed lack of evidence in this respect. Similar concerns arise with the use of electric scooters and moto-sharing, such as the displacement of active travel modes, road safety issues and the growing conflict over pavement space in many cities.

In order to conclude, new TDM strategies should incorporate certain measures depending of the level of MaaS implemented in the transport system (0–4), the stage of penetration of autonomous and electric cars (percentage over the total car population) and variables conditioning free-floating carsharing like for example, the on-street parking availability.

Planning TDM Strategies for a Transition Time

Despite the progress in the electric and autonomous vehicles manufacturing and the current implementation of collaborative and connected mobility systems, there are three premises that TDM strategies will have to work with:

- 1) The co-existence of more than a decade of conventional transport systems with more advanced ones.
- 2) The impossibility of advanced transport systems, like many MaaS operations, to independently self-manage taking into account only their economic interests.
- 3) The need for an administration and regulatory framework, mainly in cities, able to manage transport demand by ensuring environmental sustainability and social equity.
- 4) The need, through new technologies, to encourage ride-sharing in addition to shared vehicles.

Until now, advanced transport systems (like carsharing systems) have been implemented with little regulation in cities. The market share of the FFCS system, for example, is very small compared to other modes of transport, but the increased use of autonomous electric vehicles or robo-taxis may change completely this scenario.

TDM future strategies should be based on transition phases, depending on the urban and socio-economic structure of each city and its previous public transport systems. Public local administrations should lead the design of a “level 4” MaaS to manage and coordinate the mobility infrastructure. Additionally, future TDM strategies should support pull measures over push measures, giving priority to individual incentives change behavior. Today real-time and on-demand information is easily available and information of individual movements can be tracked through GPS systems and smartphones. Therefore, the incentives policy should be based on sustainable individual behavior (sharing trips, using public transport, taking an electric taxi, etc.), being complemented with push measures such as road and parking pricing and fuel taxes. The lack of accurate information on users' behavior changes had been until now the weakest part in the assessment of implemented TDM measures, but ICTs have changed this scenario. Effectiveness of new proposals of TDM strategies is supposed to be tested easily now and this fact should encourage also the design of innovative and holistic TDM strategies. In the end new technologies should be at the service of social equity, economic progress and environmental concerns.

Conclusion

This chapter was drafted in March and April 2020, in full state of lockdown caused by the coronavirus pandemic. Mobility has declined dramatically as a result of this confinement in households, and the labor market has had to experience tele-working in large scales across many cities. In some cases with very positive results, for example the reduce levels of pollution in major cities worldwide. This historic event will affect mobility behavior not only in the coming months but also in the next decade, potentially reducing commuting trips for a larger variety of jobs than ever before. New ICTs and the first experience with the first MaaS models should inform transport planners to envision and design a transport system operation that is fully coordinated by an administration (public or mixed public–private) capable of ensuring environmental sustainability and social equity.

Introduction

Planning the global movement of goods and commodities has never been a simple procedure. Cost, quality, and delivery have always been key needs in developing transportation plans. In this new period where we are confronted by uncontrollable events such as the COVID-19 virus, we must also think about resiliency as a critical global supply need. A worldwide pandemic combined with increased nationalism and more regional sourcing requirements have upended traditional thinking. When COVID-19 first hit the industry, the initial widespread response was to safeguard employees by following the guidelines set by the World Health Organization (WHO) and the governments of the countries they operate in, such as providing hand sanitizers and working from home (*Business and Financial Times*, April 2020). Given the various uncertain trajectories of these events it is important to understand how to manage through these risk factors. This chapter will focus on the overall process of setting up executable transport planning models based on transport policies and plans for the global movement of goods that are relevant to the details of the business at hand. Given the challenges we face today, there needs to be a vision and road map using some key principles to be successful.

The need and use of transportation services for the movement of goods must take into consideration all expectations of the party paying for these services. Some requirements for transportation services must satisfy a primary need such as speed, cost, quality, and reliability. At times requirements may shift at different points in the supply chain as well as the external business factors that may influence transport requirements.

This section will provide the basic instruction in order to apply a method for supporting transportation requirements in a business startup. This includes an overview of some typical requirements that would need to be modeled under given assumptions. This also will include a series of steps with the outcome being a successfully planned and implemented transportation system for the business at hand. The chapter will also provide some insights on various control charts and modeling concepts to allow for the user community and all stakeholders involved to have a good understanding of the factors being considered when planning transportation for goods movement.

Risk Factors in the New World Related to the Global Movement of Goods

With all that has been taking place in 2020 related to the impact of the COVID-19 virus, there are several risk factors that need to be considered as you look across supply chains as they relate to transportation planning for the future. Change is inevitable and the old global supply chain playbook that was in place being used by many US and multinational companies is now being rewritten to cover new factors including how to deal with various risk factors as it relates to pandemic conditions. We have just experienced and are continuing to experience the impact of the COVID-19 virus across the supplier base, transport services, and the customer demand over the past months. The past practices and process controls that used to manage transportation and planning aspects of the business will have to change to accommodate for a well-managed transportation system.

During the initial phase of the COVID-19 virus, the supply chain and transportation issues first began with sourcing goods from the People's Republic of China and then expanding to Hong Kong immediately after the Chinese New Year. During this period, firms experienced a reduction in the supply of air transport from this key manufacturing and logistical region. This had a large impact on

the amount of goods that could be moved by air. This was caused by the drastic reduction of passenger aircrafts from the region with only limited freighter aircraft flying. Keeping up with the day-to-day challenge to be sure that all demand requirements are met drove the cost of air transport up by 300%–400% from Hong Kong and China airports to the United States during the first months of 2020 ([FreightWaves Newstex Finance and Accounting Blogs, 2020-05-21](#))

One of the key factors contributing to the disruption of the transport systems was the human factor. So much of the activities require interchanges/exchanges of goods and documents which go from one person to another. Increased data analytics and the digitalization of information flow will accelerate changes to transportation planning but there is still a need at this time for skilled individuals to manage their interactions. Additional factors that came into play were airport operations scheduling personnel limitations and limited hours and days of operation. This then spread onward to the United States and Europe as the effects of the virus impacted operations both on the ground as well as local delivery requirements and operations for local trucking services to have personnel and operations to accommodate normal demand.

General Risk Factors to Consider

- Environmental risk: Where across the supply chain as a whole is it vulnerable to external forces? While the type and timing of extreme external events may not be able to be forecasted, their impact needs to be assessed.
- Supply risk: How vulnerable is the business to disruptions in supply? Risk may be higher due to global sourcing, reliance on key suppliers, poor supply management, and so on. It is critical that given recent developments in tariff changes, shift in manufacturing capabilities (i.e., sourcing product Vietnam rather than China) and COVID-19 type disruptions that adequate alternatives exist when needed.
- Demand risk: How volatile is demand? Does the “bullwhip” effect cause demand amplification? Are there parallel interactions where the demand for another product affects the demand for ours? This has become a serious issue during COVID-19 for the US retail market. Once goods began to move into the North American region in late February, the US retail came to a standstill due to the initial days of COVID-19. By early March, most US retailers had closed their stores. This caused a bottleneck in getting goods into the US distribution centers due to stoppage of local air, sea, and trucking operations.
- Process risk: How resilient are our processes? Do we understand the sources of variability in those processes, for example, manufacturing? Where are the bottlenecks? How much additional capacity is available if required? Companies that have achieved a level of automation in the management of transportation transactions were better positioned to handle the process challenges of COVID-19. During this period while employees were forced to work from home companies that still relied on manual, paper systems for transportation planning and transaction processing had real challenges replicating the environment. Companies that had already migrated to some form of transportation planning and execution systems were able to minimize disruptions.
- Control risk: How likely are disturbances and distortions to be caused by our own internal control systems? For example, order quantities, batch sizes and safety stock policies can distort real demand. Our own decision rules and policies can cause “chaos”-type effects. During the early stages of the COVID-19 virus the information was not clear as to what the conditions were day to day in China and its effect on Hong Kong for air and sea transport. It was critical to rely on multiple sources (Carriers, Forwarders, other shippers, and contacts) to determine what the current situation was on the ground. It was a daily process to collect the communications from various sources and provide a summary to the management team to explain the conditions and impacts on transportation planning and execution ([Coyle, 2011](#)).

Transportation Planning Characteristics

Several characteristics need to be taken into consideration in order to properly plan the transportation required. These characteristics are outlined below.

- Time sensitivity is an important factor to take into consideration while looking at the transportation requirement. The same product can potentially move in various time methods to minimize cost if scheduling allows for slower methods or modes of transportation. The same cargo can be moved from a factory to a destination via air or sea depending on the time built in the overall supply chain for transport days.
- Distance: How far will the goods need to travel from origin to destination? Will transport be completed in hours, a day, or several days or weeks? This needs to be taken into consideration when performing inventory planning of the goods being shipped.
- Domestic or international: Does the transport require the movement of goods over an international border? If the goods are crossing an international border the proper documentation and markings on the goods need to be included in the process. Documents such as a commercial invoice, packing list, and certificate of origin are common documents required. Factors such as pandemic related country restrictions may become a factor in this decision.
- Commodity: What is the product or goods being transported? The type of commodity will have big influence on the types of service available which will be reflected in the service days and cost of the transportation service.
- Volume/frequency: The volume or amount of product to be transported as well as the frequency of how often transport services are required are two key factors that will drive the pricing structure for transportation. More frequent higher volume shippers will

enjoy benefits of lower pricing due to commitment on volume and regularity of shipping. Carriers and folders will always honor these types of customers in that they can plan their base business around such steady volumes

- Macro-market conditions: Several macro-economic market factors must be taken into consideration at any time during planning of transportation requirements for the movement of goods to facilitate a business supply chain. These factors tend to have different types of life cycles and influences on the overall cost and service quality of a transportation system or method selected. The globalization of industries has in some ways created macro-economic forces on product supply and transportation. There continues to be a downward pressure on price of service forcing competitors to handle business at extremely low margins to compete. Customers requiring the use of transportation services have been able to take more control given the increased digital information and communications available today as tools to aid the procurement activities (Wang et al., 2018).

Method for a Business Startup: Definition, Configuration and the Impacts on Transportation Planning

Process mapping is not a new technique for analyzing operational efficiency. Its effectiveness rests in the ability to pictorially portray how seemingly disparate processes are connected; to illustrate the essential information needed to drive the work; and to ultimately illustrate how process flow relates to organizational roles and responsibilities (Martin, 2005). Below is an outline of the project deliverables needed to get through a successful startup to a steady state of operations:

1. Determine the scope of transportation services required
 - a. Provide objective, professional guidance, and support in the area of supply chain design and implementation for Phase 1 operations of the company direct to consumer business.
 - b. Apply all knowledge, analytical skills, and industry contacts to facilitate result-oriented outcomes.
2. Defining Phase 1 operational objectives/deliverables
 - a. Document business requirements and assumptions for Phase 1 operations.
 - b. Configure supply chain model for Phase 1 operations as defined.
 - c. Design and implement the required operational application systems for Phase 1 operations.
 - d. Sourcing, order management, inventory management, and other management requirements.
3. Supply chain physical distribution modeling
 - a. Profile and documentation of all business requirements and modeling assumptions.
 - b. Sourcing strategy—buying terms, trade compliance, transport from supply sources.
 - c. Packaging strategy—bulk to consumable unit repackaging, kitting services.
 - d. Stocking model—strategy, volumes.
 - e. Demand management strategy—order cycle requirements for Phase 1 customers.
 - f. Physical distribution modeling.
 - g. Define/document each segment of the supply chain (all stocks and flows).
 - h. Determination Phase 1 assumptions and model for physical distribution to support business startup.
4. Supply chain operations systems determination
 - a. Profile and document business process assumptions to support Phase 1 business operations.
 - b. Define the scope of Phase 1 system processes required to support.
 - c. Procurement, international/domestic transport, trade compliance, repacking, warehouse/inventory management, CRM, order processing, shipment tracking.
 - d. Define decision making criteria to select an overall IT/systems strategy and select each business application required for Phase 1 operations.

Tools to Assist in International Transportation Planning for the Movement of Goods

Consider for a moment how the conventional organization processes orders goods. Typically, there will be a sequence of activities beginning with an order entry. The point of entry may be within the sales or commercial function but then it goes to credit control, from where it may pass to production planning or, in a make-to-stock environment, to the warehouse. Once the order has been manufactured or assembled, it will become the responsibility of distribution and transport planning (Martin, 2005).

Project Management

Fig. 1 is an example of a project plan format (Gantt chart) used to define tasks and manage each task toward project completion. This tool helps to define each project task, ownership, and timing. This format also assists in developing the overall project plan and timeline to get to the implementation of Phase 1 operations.

Figure 2 Order cycle metrics. *Source: Author created.*

Supply Chain and Transport Process Modeling

Fig. 2 illustrates the overall business process and each major subprocess. The first step is to organize the business process into a series of major processes and some other processes. Each major process represents a cash to cash segment of the business. Each subprocess represents a process step or segment of the overall business process. Each subprocess step is defined by determining the process start and process end. It is important to also understand the base unit of measure that is being used. This could be per unit, per piece, per carton or another unit of measure as defined by the company.

Cycle time is critical to measure in both absolute time from start to finish as well as variability around the mean of the cycle time. It is also critical to measure the defect rate in the process to be sure that time is not wasted on rework items such as reshipping re invoicing, and so on.

Fig. 3 is an example of a specific business process step within an overall supply chain. This example is the subprocess of moving goods from source to market region warehouse. This is one subprocess step within the product procurement cycle. Each process step uses a similar template to capture key characteristics for each supply chain process step for the company business.

Other modeling tools to consider when planning transportation are shown below:

- Procurement and sourcing practices—single sourcing SKUs will be scrutinized to be sure the supply chain is secure and consider alternative sources if needed.
- Supply network design—near sourcing will come back into play to shorten the process segments required to get goods from sources to markets.
- Supplier monitoring—24/7 supplier monitoring will become the standard to detect early defect conditions.
- Demand drives transport needs.
- Macro factors—detecting changes for influences such as the COVID-19 virus, political conditions, or other macro conditions that may disrupt the transport services.

When considering the best configuration for a new business startup there are several factors that must be incorporated into the transportation planning. The business configuration will drive the types or levels of transportation required for the complete supply

Business Process Step

Shipping goods from Factories to Market Region DCs - Once goods are produced they are exported to market region distribution centers

Profile

- Service Providers: Air/Sea transport providers
- Annual Spend:

Q1 Accomplishments

- Evaluated possible Supply Chain Visibility Tools and created a process flowchart
- Supported the FOB and Lead Times enhancement development
- Completed the initial shipments for Samsung using the Shanghai bonded warehouse
- Completed rate review reducing air transport cost

Q2 Plans

- Next steps regarding Supply Chain visibility
- Complete pricing review for upcoming season
- Rework Management – review invoice error log to spot and act on root causes
- Convert delivery rate basis from pieces to weight (kgs)

Key performance indicators

chain (Martin, 2005). Transportation planning and execution required for the complete business process will include the need to move materials and/or finished goods from place to place dependent upon specifications including:

- Subvendor to vendor transport—usually commodities. Often the transport requirements for moving goods from a subvendor to a vendor are for raw materials considered commodities in raw form. Examples would be rolls of steel, rolls of fabric, large bulk volumes of oil, and raw minerals. During the early days of the COVID-19 pandemic, textile mills in Italy had shut down limiting the availability of fabric for garment manufacturers.
- Vendor to distribution center—tends to be the finished goods for the business. This transportation requirement can range from international air or sea to domestic truckload, less-than-truckload (LTL) or parcel (small package) depending on the type of commodities. Some business relationship may require direct shipping from the vendor or factory to the customer.
- Distribution to customer shipping requirements continue to become more and more stringent with many customer specific requirements. Customers today are now sourcing not only locally within country but also within a geographic region as well as on a global level. This requires customer specific delivery from not only distribution centers but potentially other points in the supply chain to be taken into consideration when planning transportation for customer requirements in general and will include customer to distribution (returns).

To satisfy the business requirement for each segment of transportation it is important to be sure all key characteristics that drive the service quality, speed, and cost are considered. Such transport requirements will need to be considerate of factors such as unusual size or weight per shipment based on the type of commodity being transported from sub vendor to vendor also the consideration of the timing and quality of service is a factor as well (Arroyo and Holmen, 2017; Reichhart and Holweg, 2007).

Outcomes—Activities Don't Matter, So Don't Measure Them!

Proper metrics are required to immediately detect potential issues. These metrics are derived from the key drivers that impact the success of the transport system in place. The drivers tend to be related to cost, time, and quality of service. Firms can become focused on activities and effort that are put into a project or initiative to solve a problem rather than the outcomes. Managing and measuring of transport activities is an art unto itself and firms that lose sight of the reason why proper metrics for important activities are critical can have detrimental effects (Herden, 2020).

So what is important to measure? One method in the transportation planning process is to break down the key metrics through benchmarking to find the largest drivers of the overall process goal (Reh, 2019). If specific numeric values, we are looking to measure are cost related, then we need to look at the key drivers that would most highly influence the cost such as distance shipped or the weight of the product being shipped.

Objective Factors

When we think about objective factors that are driving transportation cost, the Pareto method to define these factors is used. By isolating each variable in the transportation equation, one can determine what the largest key drivers are. Key drivers to solve are cost per unit shipped or quality of one aspect of service (tendering, invoicing). Key drivers for transportation include commodity type, weight, and distance.

Subjective Factors

Subjective factors of the performance of a transport system or process can be the experience of the participants that are impacted by the activities. Participants can have different focus depending on the influence. Focus can be on only cost, time, capacity, and quality of services or any combination. A subjective view can be the baseline or starting point—all be it a perception or view. Having a subjective point of view to progress to a more objective point of view on transportation factors that are critical to the performance of the transport process. Sometimes samples can be used but may not represent the overall population of the activity.

Subjective inputs could be anecdotal information suggesting that “costs are going up” or “shipments are more frequent.” These are usually suggested by individuals involved directly or indirectly in transport moves.

Conclusions—How do You Measure?

With the rapidly changing global environment we are facing new challenges and it becomes extremely important to evaluate the transportation planning systems and execution systems to similar companies in your industry and compare to other industry sectors. This becomes critical with such rapidly changing requirements due to factors such as influences of COVID-19 pandemic where material handling and human interaction around products and equipment within warehouse internal operations now must be rethought to include this additional risk factor.

The case for benchmarking suggests that a particular process in your firm can be strengthened. Some organizations benchmark as a means to improve discrete areas of their business and monitor competitors' shifting strategies and approaches. Regardless of the

motivation, cultivating an external view of your industry and competitors is a valuable part of effective management practices in a world that is constantly changing. The first step to evaluate practices must be to determine any gaps or opportunities to improve incorporating the changing conditions. Something to consider when benchmarking current activities is the level of comfort with the current system and the likelihood that changes can be adopted in a positive manner.

It is always helpful to determine what is “best in class” for like companies in order to compare a firms’ practices to a “best in class” level. This can be done by internal or external resources. Some corporations set process standards for all divisions to achieve based on best in class benchmarking. Determining the gaps between the current system and the best in class can create a roadmap to identify the gaps to close between the current system utilized and a best in class system.

When looking at measuring the performance of a transportation system it is important to understand the key drivers that need to be measured. There are usually a few primary and secondary metrics that will drive the majority of the behavior you are modeling. These metrics are distance, weight, type of commodity, as well as supply/demand characteristics of the macro-market for the transportation route. Measuring key performance indicators should be the activities or aspect of the transport that are driving the critical behaviors. These factors can be identified both subjectively as well as objectively.

The impact of the COVID-19 virus influences all activities. The new risk factors that need to be considered will require a rewrite of the playbook. Regional supply chains will become much more attractive over global supply chains in order to limit risk factors in today’s environment.

Introduction

This article provides a framework for understanding the principles and good practice in public transport network planning. It begins by considering the objectives and purpose of network planning before examining the role of economics in underpinning network planning activities and the higher level objectives of public transport provision. The entry then turns to the principles of network planning, including a discussion of timeframes and the necessity of understanding how network planning outcomes fit into the demand for travel by the end user. This is followed by discussing the adjustments necessary to provide good network planning for areas of low demand. The penultimate section examines issues and areas where more attention is needed in the future. The entry ends with a short contribution on the role of public transport in the future, in the post-COVID-19 world.

Objectives and Purpose of Network Planning

The nature and scope of network planning tasks are partly defined by the institutional set up of the area under consideration and partly shaped by the mode being planned. However, in defining the scope it is imperative that the area under consideration be carefully defined and that the aspirations for the level of service be clearly outlined. The planning needs to understand how existing resources contribute to the different goals of network planning and recognize that planning in the short, medium and long term have different issues.

The definition of network planning tasks need to be sensitive to the goals and objectives which should include allowing public transport operators to provide services that customers are willing to pay for, should support social policy as well as providing efficient transport and contribute to an overarching goal of transport sustainability. At all stages of network planning, it is important to define the indicators of success that relate the aspirations of the objectives to the outcome of the network planning. Monitoring change is necessary and the definition of key indicators at the planning stage is important if post implementation evaluation is to be targeted.

Public transport networks influence land use structure and vice versa. In network planning, these need to be positively considered so that land use and public transport strategies become mutually reinforcing. This is seen in cities where new public transport infrastructure is being established when, for example, a new metro is associated with the building up of densities around proposed stations or where new stations are associated with deliberate transit-oriented design (TOD) developments to exploit the greater accessibility of the new transport link. It is also seen where new land use developments, for example, the building of a new housing development, where new public transport links need to be provided if the development is not to become car-centric. In particular a strong public transport—land use strategy will connect the component parts of the area under consideration so that public transport can shape urban growth. This is because the market will recognize how public transport is useful in providing necessary connections. One way in which a public transport network can be extended is through the use of complementary modes such as micromobility solutions such as (e)bicycles and scooters and carpooling for the “first and last mile” (1LM) of a journey.

The institutional framework which determines how public transport is organized and which body is responsible for its delivery does make a difference to the objectives and purpose of network planning. The institutional framework is really a continuum going from one extreme of market competition to another extreme of coordinated planning. In the market competition end of the continuum there is little role for network planning with operators determining the price and quantity mix of public transport provision. As a result, users will be faced with large differences in service levels as operators will provide more services on routes with high patronage. Experience of market competition in bus services (in the UK and in New Zealand) led to excess capacity being

provided on “good” routes, increased innovation for services which added to the operators’ “bottom line”, more efficient production, but a network that was not stable and for which it was difficult to provide integrated ticketing and comprehensive passenger information. At the other extreme of coordinated planning, there is a significant role for network planning and the objective of public transport being a viable alternative to the car can be met through the provision of an integrated network with operators being able to exploit economies of scale. Whilst coordinated planning allows the development of long-term planning often based on the cross subsidy between routes it also provides the opportunity for the development of monopoly outcomes and weak market incentives. In reality, institutional frameworks tend to be located somewhere along this continuum with network planning being more relevant to the coordinated planning—sometimes called the public service—approach.

The institutional framework also has other impacts on the success of network planning. The coordination of the bodies responsible for public transport regulation and delivery is an important constraint on success. Regional organization of public transport is often cited as an important success factor but it is in fact a necessary but not sufficient factor (it is possible to have regional organization but fragmented coordination which gives rise to less favorable public transport planning outcomes). Network planning should at a minimum be concerned with the spatial area of the labor market if it is to avoid cross boundary issues for users who are commuting. An institutional framework will be more successful if it works to provide supportive and complementary policies to reinforce the overarching transport policy—often called “push and pull” policies—such as expensive or limited car parking in an urban center. Finally, stable funding is a pre-requisite for good network planning as users are not sympathetic to frequently changing networks.

In summary therefore, networks that perform well are characterized by sufficient stability so that the public transport system can influence urban development and allow users to create and maintain sustainable transport patterns, a robust and simple structure which provides public transport options for all citizens.

The Role of Economics and its Impact on Network Planning

Economics is fundamentally about the allocation of resources. For individuals making trips, they are broadly trading time and money when making their decision as to how to travel. For example, if a journey by public transport was to take ten times longer than by car it is likely to become a car journey. Car journeys may be shed in favor of a public transport trip if there is no parking at the destination or if parking is expensive. Governments have a higher level role in ensuring mobility for their community is undertaken in ways that meet the higher objectives of policy for example, in relation to congestion or environmental pollution. Governments also have to make the connections that are unlikely to be made by individuals, in particular the links between land use and transport planning and the links between public transport and health.

Individuals are typically only aware of the trips they make. They are not usually aware of the network that makes up the public transport system—the network that provides accessibility to destinations that are part of daily activities. In contrast, governments should have a commitment to the network as a whole and focus on enhancing the “network effect” when undertaking network expansion or improvements so that new projects and enhanced corridors add more to the network than if taken in isolation.

Objectives for Public Transport

Public transport policy objectives are multidimensional. They encompass economic aspects, such as the reduction in congestion through mode shift away from car travel, environmental sustainability as the transport sector is a significant contributor to greenhouse gas emissions and social/quality of life aspects including the positive health impacts from public transport use (more activity, walking to access public transport, and egress to final destination) and equity, social justice, and engagement impacts on social inclusion.

People choose to use public transport when it is high frequency, when the journey times compete well with a car journey and when they cannot park at their destination; that is when the experience can be made as seamless as possible. Frequency is important because network planning is all about understanding the coverage versus frequency trade off. If budgets are fixed, then more frequency means less coverage and vice versa. This links of course to the objectives for public transport. If an objective is patronage growth or environmental impact reduction, then the network planning must deliver higher frequency since this is most likely to get travelers out of their cars and onto public transport (Currie and Wallis, 2008). If an objective is to have greater equity or social inclusion, then the network planning must deliver coverage. To meet both objectives means that network planning needs to find the optimum balance between frequency and coverage, ensuring that individuals losing coverage are provided with accessibility in a way alternative to conventional public transport services.

Of course, the trade off between coverage and frequency flows through to performance measurement which only makes sense relative to the goals and objectives of the public transport policy.

Principles of Planning

In the short-term, network planning focuses on buses. In multimodal systems, in the short-term any rail based system is fixed: the timetable can be changed, the frequency and stopping patterns can be changed but not the route. So for urban areas in particular, bus

provides the flexibility to meet changing or new “needs” of accessibility in the short-term. Hence, the principles of this section relate to network planning for the bus network.

There are two approaches to network planning—the tailor-made approach and the ready-made approach (Nielsen et al., 2005). The tailor-made approach fits the needs of different users and fits the needs of different times of day whereas the ready-made approach provides a simple and stable network of lines throughout the day but varies the frequency and vehicle size according to the needs of different users and times of day (see Fig. 1).

The Tailor-made approach

A dense, normal frequency network most of the day

Reduced and low frequency network on holidays

Express lines in peak periods

Evening and night lines

Service lines for the elderly and disabled

The Ready-made approach

A basic high frequency network most of the day

Same network, reduced frequencies on holidays

Same network, higher frequencies in peak periods

Same network, reduced frequencies evenings and nights

Local lines and demand-responsive services for all users

One stable, easy-to-use network for all at all times

Figure 1 Two different approaches to network design (Nielsen et al., 2005, p. 35).

The problem with taking the tailor-made approach is that services and networks can be very complicated to supply and an inefficient use of the total resource for public transport. Moreover, for the user, it can become complicated to understand with different networks from the dense, normal frequency network that exists for most of the day, a reduced network at weekends, a different but also reduced network for evening and night buses and so on. This has led to the development of the ready-made approach which develops the network in two stages. The first is the development of the trunk routes—those lines within the network which will have high frequency because of heavy demand and which will attract priority measures on the road network. This stage requires the concentration of available resources. The second stage is to provide more dispersed and flexible (demand responsive) services so as to serve all citizens. The major task of network planning is to find, for the available budget, the right balance between these—the frequency and coverage trade off discussed above. The second stage of development is discussed in the next section and is concerned with areas of low density and demand.

In the first stage of development, the ready-made approach argues for the concentration of resources on corridors, using timetable coordination to increase the frequency as density increases. Concentration of resources means removing the “wiggly” routes so that, for example, two low frequency lines which operate in close proximity should be amalgamated to provide one more direct route with enhanced frequency and no change in resources expended. The design principle is “one section one line” so as to provide a simple network, moving away from the single seat approach whereby many destinations are served by lines with no transfer. The “one section one line” approach has operational advantages since an operational disturbance, for example a traffic accident, only affects that section and is not transmitted to the rest of the network. The network planning skill in the “one section one line” approach is to link the sections so as to have the minimum number of routes. The best way of doing this is to link sections which have similar demands on different sides of the urban area center so that services do not have to terminate in the urban center where space is at a premium and where termination would simply add to congestion. Simplicity also saves resource with wiggly routes with many stops costing up to 250% more than a straight line with centrally placed stops (Nielsen, 2005, p. 133).

This first stage of development of the network requires a good frequency on these trunk lines. There are three main classes of frequency (Balcombe, 2004). The “forget the timetable” frequency is one whereby users do not need to consult the timetable and they arrive at stops randomly; in London, UK, this has been empirically estimated to be between 6 and 12 departures/h. The “fixed minute” timetable is reserved for lower demand lines and in Norway has been empirically determined as an hourly service. The final category is the frequency for flexible on-demand services where demand cannot support an hourly service. Each of these different frequency types have operational necessities: the “forget the timetable” frequency must have services which are spaced at equal intervals and the “fixed minute” service must keep to its timetable. The approach to flexible transport services is discussed in more detail below.

Seeking to provide an optimum frequency for trunk lines is another trade off for the network planner. In the peak, a “forget the timetable” frequency is essential. Increasing the frequency much beyond this can give rise to diminishing returns with smaller headways potentially leading to bus on bus congestion. Typically, if demand is such that a headway of 2 min or better is needed, then it is a better alternative to open up a new line, linking centers which are not currently served by direct routes. This not only releases pressure on the existing lines as well as providing alternative travel destinations but also has the impact of growing the network through exploiting the network effect. An alternative way to release pressure is to plan to introduce a high capacity route in the form of Bus Rapid Transit (BRT) infrastructure although this is not usually feasible in the short-term; a more recent compromise is “BRT lite” which is less likely to include fully segregated busways.

Whilst difficult to do effectively, network planning should seek to exploit the timetable in a way that as lines converge toward the city center, the frequency of service increases. The skill here is to organize the services from the outer suburbs which are necessarily less frequent, to build to a service pattern of equal intervals for users as the services from suburbs converge toward the city center.

In the ready-made approach, frequency is the key variable used to adjust for demand. Operators will supply more frequency in the peaks, reduce the frequency in the peak shoulders, and reduce again for evenings and holidays. This way a simple and stable network is maintained that meets the needs of users.

It is worth noting that if frequency is good, walking further to a stop will not have a big impact on the combined walk and wait time. Indeed, there is evidence that users will walk further to a more frequent stop (Mulley et al., 2018). It is also important to have good frequency across the network—both radially and across the city—this speeds up journeys and makes interchange between lines short.

The “elephant in the room” of the ready-made approach to network planning is its reliance on interchange. With a simple, stable network using the “one section one line” principle, it must be accepted that interchange will be needed between lines operated by the same mode and, in multimodal systems, between lines operated by different modes. Interchange, of course, allows the best of the mode to be exploited and transfer to another mode when it is better at providing the desired service. Accepting interchange means that services do not need to concentrate on providing single seat journeys and allows greater coverage. The planning skill is to maximize the number of direct journeys by knowing what passengers want and having high enough frequency that interchange is not a barrier to travel.

Interchange can be used to release resources. Bearing in mind that super high frequency can lead to bus on bus congestion, a tailor made network can be redesigned so that a previous design of single seat services from a number of suburbs, all converging to a common route at the city center is approached, becomes one where interchange is made at the start of the common route. This can release resources to improve the frequency of lines to the suburbs and provide a frequency that does not give rise to congestion as the city center is approached. Even with having to interchange, total travel does not need to increase as shown by Nielsen (2005, p.110).

Recognizing that transfers and interchange are necessary in a ready-made approach means that network planning should endeavor to minimize the cost of interchange. This can be done by ensuring timetable coordination, ensuring that route information is presented accessibly, removing fare penalties and creating short and easily understood interchanges. The empirical evidence is that higher levels of transfer are associated with higher public transport modal shares—showing the benefit of the network effect (Terzis and Last, 2000).

Areas of Low Density and Demand

In the second stage of development, the network planning strategy needs to take an alternative approach. Where there is low density and/or low demand, a strategy of a high frequency, stable network will not work: users would need to walk considerable distances to stops and providing high frequency would be an inefficient use of resource.

Strategies such as the “hub and spoke” approach of airlines can be used successfully when arrival and departure times to key interchanges are planned. More personalized, flexible transport services can be planned, typically using smaller vehicles, as an important part of the overall network.

Flexible transport services (FTS) can be used to feed into a planned network of fixed route services. FTS are usually operated with smaller vehicles and are provided on-demand. It has been argued that the family of FTS can be extended to include taxis and private hire, on demand car services such as Uber and Lyft and car pooling (Nelson and Wright, 2016). Flexible feeder services can help to secure the viability of the fixed route service as well as extending accessibility beyond the walkable catchment of the fixed route service. Typically, subsidy per passenger for this type of service is high even though the cost of operating smaller vehicles is lower than that of the “big bus” on the conventional fixed route. CallConnect in Lincolnshire, England is an example of a successful service. Established in 2001 and continuing to the present, CallConnect is used to feed a quality network of fixed route local bus services designed to improve transport links to destinations throughout the county. The 6 FTS feeder services offer guaranteed connections (with the availability of a taxi as a last resort) and the service offering also includes 14 separate area-based FTS services. Importantly, the flexible feeder services help secure the viability of the fixed route services and have resulted in the level of unmet need in the communities served being reduced by 90%. CallConnect (described in Wang et al., 2015) replaced a less effective fixed route service when it was introduced and the subsidy required by CallConnect is approximately the same as was required for the fixed route services it replaced.

Issues in Planning

The nature of public transport is changing as the boundaries between traditional fixed route services and private shared modes increasingly blurs, particularly as the new mobility modes and the influence of the sharing economy (manifested *inter alia* as bike-, car- and ride-sharing) become more prevalent. Passengers continue to show an increased preference for App-enabled personalization of travel opportunities (Nelson and Wright, 2019). The emerging Mobility as a Service (MaaS) context is helping to shape the future landscape for public transport and making the case for public transport to be situated at the core of MaaS offerings (Hensher et al., 2020).

Providing a network of lines is only part of the network planning task. However, some tasks are only possible in the longer term (more than 5 years), such as urban and regional structural planning and investment planning for new infrastructure. Other tasks, such as budget planning, fares policy and operational aspects are needed in the short-term to facilitate the delivery of the network plan. Changing the network plan takes time (between 2 and 5 years) and should be undertaken along with an analysis of the previous network from monitoring data and with information on then current mode choice behavior.

Conclusions

Good network planning should take account of the urban structure in locating demand, existing infrastructure and networks. The creation of a ready made network providing a simple and stable structure will build on the mutually supporting planning of land use and transport. In all cases, it must be remembered that the journey on the vehicle is only a small part of the overall journey so far as the traveler is concerned.

It is important to recognize that whilst interchange is seen as a penalty, a network plan predicated on interchange can provide access to more destinations with fast journey times. As a result, interchange based network plans can provide a higher use of public transport overall.

Whilst outside the scope of this entry, it is worth noting that different topographies can cause constraints: urban areas bisected by rivers, terrain subject to many changes in gradient. Also the institutional arrangements of the area—its history, its politics—can also act as a constraint on what can be done.

At the time of writing the world has experienced a sudden collapse in trip making behavior on account of the COVID-19 global pandemic. Following the introduction of stay at home directives global public transport usage has collapsed; Australian public transport usage, at April 2020, is 80% lower than 12 months earlier and in the UK, public transport usage is more than 90% lower in

some areas. With this comes a consequent fall in revenue for public transport with risk shared amongst different parties depending on the institutional framework but ultimately most of the risk will fall on governments.

It is clear that public transport patronage is not going to quickly rebound to pre-COVID-19 levels; this is primarily because of perceived anxiety over the potential health hazard of being in close proximity to others. Social distancing on public transport is difficult for a system designed to be mass transit. Advice on physical distancing varies and ranges from 1 to 2 m, depending on local and national contexts. But even with more relaxed distancing (1 m distance + gap between people in each seat row) a capacity of around 30% for buses and 50% for trains may be the best outcome that can be achieved. If public transport is to retain as many former passengers as possible, the traveling peaks need to be spread although it will be challenging to accommodate staggered start times be it for education, retail or workplaces. Earlier work on spreading the peak may be relevant here with, for example, a study of peak spreading in the University sector can be found in [Daniels and Mulley \(2012\)](#). Other measures that may be introduced include a move to rear door boarding, temperature checks, banning of cash payments, marshalling of people queuing, use of masks (where recommended) and provision of hand sanitisers. It is also likely that globally there will be greater working from home where this is possible.

There is compelling evidence that liveable cities need good public transport (achieved by good network planning) and the current imperative is to ensure that future public transport is safe, comfortable, and convenient. There may need to be a pause on larger mass transit infrastructure projects in the shorter-term in favor of a greater focus on enabling seamless intermodal journeys.

Biography

Corinne Mulley was the inaugural Chair of Public Transport at the Institute of Transport and Logistics Studies at the University of Sydney. She is now Professor Emerita at the University of Sydney and an Honorary Professor at Aberdeen University. Corinne is a transport economist and is active in transport research at the interface of transport policy and economics, in particular on issues relating to public transport. She has provided both practical and strategic advice on transport evaluation, including economic impact analysis, benchmarking, rural transport issues, and public transport management. Corinne's research is motivated by a need to provide evidence for policy initiatives and she has been involved in such research at local, state/regional, national/federal and European levels.

John Nelson is Chair in Public Transport at the Institute of Transport and Logistics Studies (ITLS), University of Sydney which he joined in 2019 from the University of Aberdeen where he was Sixth Century Chair in Transport Studies and Director of the Centre for Transport Research. Before moving to Aberdeen in 2007 he was Professor of Public Transport Systems at Newcastle University, UK. John is particularly interested in the application and evaluation of new technologies to improve transport systems (with a particular focus on public transport and shared transport solutions) as well as the policy frameworks and regulatory regimes necessary to achieve sustainable mobility.

The Need for a Timely Perspective on Planning Transport Infrastructure

The prevailing paradigm in transport planning is often said to be characterized by an imperative to “predict and provide” (Banister, 2008). This objective quickly narrows to “provide” – building new infrastructure to meet projected demand for mobility in order to prevent future congestion. Meanwhile, the “Sustainable Transport” planning paradigm has highlighted the need to “green” the technology supporting mobility and adjust travel behavior to reduce the ecological impacts of mobility (Schiller and Kenworthy, 2018), but has not adopted any major changes in the design and planning of transport infrastructure. Alongside calls to invest less in road construction, sustainability advocates usually call for investing and building more public transport infrastructure, particularly railway infrastructure (Banister et al., 2011). But while adjusting the mix of infrastructure supply is seen to advance sustainability, transport planners have yet to consider building new infrastructure differently. This is an overly narrow approach for what needs to be done when demand for new mobility grows, the main trigger of initiatives to supply more transport infrastructure.

The current mobility landscape is very dynamic, and at times even volatile. Rapidly increasing use and promotion of non-motorized transport especially in European cities juxtaposed against the major increase in motorization levels in developing economies are two examples of disruptive trends, although in opposing directions along the sustainability spectrum. Jones (2016) for example describes the evolution of cities in North-west Europe from predominantly being car based to being more people based and this change is explained in greater detail for some European cities by Buehler et al. (2017). On the other hand, Ma et al. (2012) forecast that the growth in demand for motorized transport in China is expected to continue expanding at a fast pace.

Recent technological developments and the incorporation of information and communication technologies (ITC) into transport operations have been driving changes in mobility, and more broadly in society. The rise of shared mobility transport options delivered by companies like Uber as well as the spread of the car-sharing phenomena could transform the ways that transport infrastructure will be used in the future. Furthermore, the adoption path and pace of autonomous vehicles, which are widely recognized as a disruptive technology will likely reshape our future mobility demand and consequently our transport system (Guerra, 2016). From ride hailing to drones to autonomous motor vehicles, these new mobility technologies are still in full flux, which adds to the uncertainty currently facing transport planners. This predicament is often referred to as “deep uncertainty” (Lyons and Davidson, 2016) and succinctly explained as “we know only what we do not know” (Wall et al., 2015).

In scholarship about “planning for the future,” a new strategy for managing change under conditions of deep uncertainty has emerged according to which “a planner should create a strategic vision of the future, commit to short-term actions, and establish a framework to guide future actions. A plan that embodies these ideas allows for its dynamic adaptation over time to meet changing circumstances.” (Haasnoot et al., 2013, p. 485). This new planning approach, referred to as Dynamic Adaptive Planning (DAP) is well designed to deal with transport infrastructure, given its inflexible attributes and long lifespan. Yet this approach to developing dynamic and adaptive attributes usually refers to the plan for delivering infrastructure and not its functional design. Wall et al. (2015), for example, describe a DAP for the San Francisco–Oakland Bay bridge replacement in which the infrastructure function remained fixed. Extending the DAP process to infrastructure redesign could have opened possibilities to make the structure serve “dynamic and adaptive” mobility functions in the future.

The rigid characteristics designed into most transport infrastructure constrain both efforts to transition to low-carbon mobility (Givoni and Banister, 2013) and to advance the “sustainable mobility paradigm” (Banister, 2008). Instead of automatically reinforcing existing technology and modal functions, new modes of thinking about an infrastructure’s future can offer the opportunity to adapt original designs and thus facilitate sustainability transitions. Innovation can be triggered by a formal assessment threshold discussed in the next section.

Table 1 The Four R Framework for transport infrastructure adaptation

Strategy	Description
Renew	Refurbish existing infrastructure to continue its current transport function. May include an upgrade to increase mobility.
Redesign	Enable infrastructure to support different forms of mobility through accommodating new transport technology and/or modes.
Repurpose	Decommissioning infrastructure from its original mobility function and using the structure and its surrounding space for activities other than transportation.
Remove	Dismantling the infrastructure and removing it from the previously occupied space.

Source: Adapted from *Givoni and Perl (2017)*

Adapting the Half-Life Concept to Reassess Transport Infrastructure

Ernest Rutherford received the Nobel prize in Chemistry for discovering that the decay of radioactive isotopes can be measured through a half-life ([Rutherford, 1900](#)). This is the point when the isotope has emitted half of its radioactivity. Such a half-life measure can also reshape our understanding of transport infrastructure by highlighting the change in its physical condition and underscoring the need to reassess its future. Like radioactive decay, the deterioration of transport infrastructure is unavoidable, and the half-life offers a focus that can trigger planning for what to do about infrastructure degradation.

Once built, any transport infrastructure begins to degrade and loses some of its utility, either because it cannot support as much mobility as it did upon inauguration, or because demand declines for the mobility using that infrastructure. Action should be taken before these trends reach their logical conclusion, in order to extend the useful life of that infrastructure. Four distinct strategies to meet the future are possible, which together have been labeled the 4R Framework for adapting transport infrastructure ([Givoni and Perl, 2017](#)). These approaches are outlined in [Table 1](#). The options include: *Renewing* the infrastructure to extend its physical life while preserving its original purpose and design; *Redesigning* the infrastructure to broaden its function to supporting a different mix of mobilities; *Repurposing* the infrastructure to transform its function toward supporting a non-transport use; or *Removing* the infrastructure completely, and thus clearing the space it occupied for other activities and new structures, or even returning the space to a natural environment.

Keeping infrastructure in a state of good repair to prolong its lifespan is a well-established transportation management practice. The most common strategy for maintaining infrastructure's future value is thus to *Renew* its existing mobility capability. But as future mobility demands evolve, and new technology diffuses, going beyond refurbishment to introduce different forms of capacity for mobilities can arise through infrastructure *Redesign*. Sometimes, this strategy accommodates multiple modes on the same infrastructure. At other times, a new mode is substituted for the original one, changing the role which that infrastructure was intended to play.

Deciding to redistribute the space that had been occupied by infrastructure to another purpose besides transport can create a new sense of place, often enabling the surrounding space to be redeveloped in ways that would have been incompatible with most mobility infrastructure. This approach is embraced by the strategy to *Repurpose* infrastructure for non-mobility uses. And an even more dramatic shift can occur when transport infrastructure is completely dismantled and extracted from the space that it once occupied, following a decision to *Remove* it.

Each alternative scenario should at least be considered as transport infrastructure approaches its half life. Then, the most plausible and desirable future can be identified, and the adaptive path toward some degree of change in that infrastructure's form and function can be planned out. Realizing greater levels of adaptation can be facilitated by decoupling the base of transport infrastructure from the superstructure over which mobility operates on it. This attenuation enables an optimization of durability and flexibility, attributes which are both needed to enhance infrastructure's future value and which are discussed in the next two sections.

Taking Stock of the Relationship Between Durability and Flexibility in Transport Infrastructure Development

Ancient societies have revealed little concern about the costs of building monumental infrastructure that would last forever, such as the Egyptian pyramids. Roman highways were also built to last, and small stretches of this infrastructure are still used ([Berechman, 2003](#)). But once economists introduced the practice of discounting infrastructure costs and benefits ([Parker, 1968](#)) it became common for infrastructure to be built for a fixed lifespan—after which benefits were not to be counted on. This time frame is typically set at 30–60 years after construction.

Even if its lifespan is not eternal, infrastructure's indivisibility and irreversibility do require a significant up front financial commitment. These attributes justify building *durable* infrastructure to last many decades. This same logic can also justify oversupplying infrastructure, through designing a larger than needed capacity for example, in order to meet future demand and thus avoid rising construction costs ([Zembri and Libourel, 2017](#)).

Over time, new transport technologies supplement earlier ones in meeting mobility needs, ([Grübler, 2004](#)). However, a new transport technology does not completely displace its predecessors, at least not immediately. For example, not only are railways still

operating in the “automobile age,” in recent decades they have experienced a resurgence that some have termed the second railway age (Banister and Hall, 1993). Gröbler’s (2004) analysis reveals how new transport technology contributes to meeting mobility needs through an incremental addition to established capacity that usually builds up over time.

Since each mode’s infrastructure is designed differently, investing in the upkeep of all this accumulated infrastructure often proves to be wasteful. This became evident with the decline in demand for rail travel during the mid-20th century. The development of the “car society” in the United Kingdom revealed the costs of the Victorian exuberance for building railway infrastructure to last forever. Designing durable infrastructure thus means creating structures that are difficult to adapt in the face of change.

What seemed unimaginable to Victorian railway builders, turned out to be inevitable – growth trends do not go on indefinitely. Recent evidence suggests that a similar dynamic of change could be in store for the automobile – new technologies (e.g., internet), new behaviors (e.g., ride sharing), and demographic changes appear to be shifting demand (Polzin and Chu, 2014; Stapleton et al., 2017).

Durable infrastructure also works to lock in spatial and social effects across a society. Motorways that enabled Americans to travel further and faster in the 20th century have embedded spatial and social outcomes that continue to reinforce automobile dependence during the 21st century (Squires, 2008). Such lock-in effects are compounded by the reluctance to write off fixed assets like motorways and railways even when their productivity is much reduced and external costs are growing. But periodically, concentrated change in mobility does occur.

Gilbert and Perl (2010) have defined a transport revolution as a substantial change in passenger or freight movement that occurs in less than 25 years. Such tipping points are catalyzed by disruptive transport technologies or radical reorganization of business models (e.g., deregulation) and they drastically change infrastructure’s required attributes in a short-time period. Thus, in times of rapid change, the benefit of flexibility in infrastructure design increases, and durable infrastructure’s inflexibility decreases its value by constraining its adaptation. Building flexibility into infrastructure through planning and design holds the key to avoiding both the sunk cost trap and the lock-in effects that impose future burdens on society. Thus, infrastructure that retains its value after a transport revolution can be judged to be both durable and flexible. Creating the capacity for such an optimal balance of durability and flexibility requires reconciling these two fundamental infrastructure design attributes.

Reconciling Durability with Flexibility: A Strategy for Developing Resilient Transport Infrastructure

While the challenges of developing infrastructure that can retain its value over time might appear daunting, a planning strategy that can adapt to alternative futures that emerge after the infrastructure’s half-life arrives shows considerable promise. With constraints on economic productivity and profit growing over time, investing in renewal and expansion of transport infrastructure becomes harder. This dilemma has been recognized both in transport and broader economic studies. Gifford (1994) claimed that rigid infrastructure is overvalued in urban transportation planning while Dixit and Pindyck (2000) discussed the burden created by overinvestment in a firm’s production capacity. The goal of reconciling durability with flexibility in transport infrastructure is thus both apparent and necessary. Looked at strategically, investing in transport infrastructure would make more sense if that infrastructure could be designed to be flexible and adaptable to changing needs.

An effective approach to adaptive infrastructure planning and design that combined flexibility with durability can be found in the 19th century French practice of separating the responsibility for developing transport infrastructure and superstructure. Walton (1998) details how the French state, which possessed a highly capable engineering bureaucracy, the *Corps des Ponts et Chaussées*, took on responsibility for designing rail rights of way and building their subgrades, bridges, and tunnels. This infrastructure was then transferred to private management on long-term leases, which enabled private carriers to finance and build the tracks, signals, and stations required for railway operations. *Superstructure* became the legal term used to differentiate these private fixed assets from the publicly planned and owned right of way that was identified as *infrastructure*.

By rediscovering this physical and organizational distinction in the 21st century, transport infrastructure can once again obtain the advantages from durability while the superstructure connected with it gains the flexibility to support more than one transport technology, serve multiple modes, or even enable a mix of transport and nontransport functions. Ongoing adaptation of durable infrastructure and flexible superstructure can be facilitated by enabling separate organizations to design and plan these components before and after the half-life point in time arrives. Such a strategy can accommodate adaptation to changing technology, demographics, and societal needs, as the demand for mobility evolves.

The value of Victorian rail infrastructure been enhanced using such an adaptive redesign strategy. Some railway bridges no longer used by trains have been converted to serve road transport, by reconfiguring their superstructure. And when rail travel demand started growing again in the 21st century, some decommissioned rail rights of way, which had been retained were reactivated with a new rail superstructure. Similarly, the ‘Rails to Trails’ program has adapted derelict US rail infrastructure by introducing superstructure for walking and cycling. The resulting trails preserve the transport right of way that could be further adapted to support future mobility needs (see for example Beiler et al., 2015).

Superstructures can become flexible, even without physical redesign, by organizing different uses at different times. Examples include repurposing urban motorways on Sundays for walking, cycling, and non-motorized transport, which started in South American cities (known as *Ciclovías*), and similarly in Paris for the summer holidays along the Seine (Bertolini, 2017, p. 93).

Assessing the trade-offs between durability and flexibility in each of the 4R framework’s strategic scenarios can benefit from accounting for the option value and opportunity cost of alternative designs (Litman, 2009, pp. 1-13; OECD, 2006, p. 21). Building

durable infrastructure increases the opportunity cost of removing it later, but can also augment the option value of enabling an adapted superstructure in future, even if such a design might increase initial costs. The opportunity cost of not enabling a flexible superstructure to permit future Repurposing or Redesign ought to be considered when designing new infrastructure. In a similar way, the option for removing infrastructure, because it might not be adaptable to future mobility, needs to be kept in mind.

Optimizing designs for option value and opportunity cost led to some of the infrastructure built for the 2012 Summer Olympics in London to be dismantled after the games. This strategy saved both construction and maintenance costs, while retaining the option for future reuse of both the venue and the materials that had been combined for a particular purpose at a given point in time (Brown and Cresciani, 2017).

Conclusion

Transportation asset management practices most typically embrace preserving infrastructure in its existing functionality, by assembling the resources needed for ongoing maintenance (e.g., Mohammadi et al., 2019). Although such preservation remains an important option, pursuing it as a singular goal is too limited to maintain the value of infrastructure over time, especially when the costs of a high-carbon mobility lock-in are taken into account (Givoni and Banister, 2013). Although it can be challenging to reimagine multiple alternatives at an infrastructure's half-life, planning, and designing adaptable (i.e., flexible) infrastructure will pay dividends through increasing and prolonging the value of the combined infrastructure and superstructure.

Effective and resilient infrastructure adaptation can be facilitated by relying on three key principles. First, recognizing that because an infrastructure inevitably deteriorates and loses utility over time, planners should identify a "half-life" point where options should be assessed for adapting to the future. This approach aligns with Haasnoot et al.'s (2013, p. 486) idea of an "adaptation tipping point" Second, once the half-life point has been recognized, four alternative design scenarios need to be considered. These are: *Renew*, *Redesign*, *Repurpose*, or *Remove*. These alternatives should already have been identified in the infrastructure's original design principles and even partly built into its physical form to facilitate implementing strategic transitions the future. Third, a distinction that is both organizational and technical must be made between the infrastructure (the foundation), which should be durable, and the superstructure it supports, which should be flexible.

Embracing both the temporal strategy for anticipatory renewal at or near the infrastructure's half life and the substantive analysis of four scenarios for improving utility in the future use provides the greatest opportunity to extend and enhance the value of transport infrastructure as it ages over time.

Acknowledgment

This understanding of how to adapt infrastructure to enhance its value over time originated in a collaboration with the late Dr. Moshe Givoni, Associate Professor of Geography at Tel Aviv University. Dr. Givoni was an accomplished and widely respected transport scholar who advanced understanding about mobility in those who encountered him or his work. The author would like to dedicate this encyclopedia contribution to Dr. Givoni's memory.

Introduction

The role of the media in the policy process for different transport policy measures is often questioned by scholars from various perspectives. For instance, some scholars explored the whole policy process over time and argued that the media presentation of transport policies led to some specific policy decisions and events (e.g., Norley, 2011). In fact, some scholars already assumed that the media presentation of transport policies could change the direction of a policy process and, therefore, examined how specific transport policy measures were presented by the media (e.g. Ryley and Gjersoe, 2006). But so far no comprehensive picture has been presented regarding the role of the media in transport policy planning and the transport policy process by scrutinizing the relationship between the media and the transport policy process.

This article aims to explore the role of media in transport planning and the transport policy process, based on a literature review. The Scopus database was used to select papers on the topic of this chapter. First, papers which included the word “media” in titles, abstracts or keywords, and the phrase “transport policy” in any parts, were selected. This search resulted in around 1500 papers being found. After that, the authors scanned the abstracts (and sometimes the main text) of these papers to determine the final set of papers. Papers which did not present any research questions or data analysis related to the relationship between the media and transport policy process and only mentioned this topic with reference to findings of other papers were excluded. As a result, our sample ended up having 17 papers in total.

The article is organized as follows. Section 2 presents a brief overview of the relationship between the media and the public policy process. Section 3 elaborates on the selected literature on the relationship between the media and the transport policy process, based on this overview. Finally, Section 4 presents conclusions to the chapter and ideas for future directions in this area of research.

The Relationship Between the Media and the Public Policy Process

The media is a major communication platform linking policy actors and the public in the public policy process and providing information exchanges among them. However, the relationship between the media and the public policy process is very complex, dynamic and interactive and involves a continuous interplay among numerous policy actors (e.g., politicians, interest groups), public and the media. With the development of digital technologies during the last decade, the relationship between media and other actors has become even more complex. Individuals and all policy actors can create their own news content by sharing their messages with others via various social media channels (e.g., Twitter). They do not have to rely on only traditional media and can search for numerous news sources on the Internet. But in the meantime, the traditional media outlets have been launching their new content on the Internet and incorporating social media platforms to their websites. So, in this way, the traditional media still maintains its dominant voice (Weimann and Brosius, 2015). To properly comprehend such a multifaceted relationship between the media and the public policy process, we need to probe into its two major characteristics: “reciprocity” and “conditionality” (Van Aelst, 2014; Voltmer and Koch-Baumgarten, 2010).

Reciprocity of the relationship between the media and the public policy process means that the media can influence the public policy process, while the reverse is true as well. That is to say, on the one hand, politicians may change the direction of a policy process or their policy communication according to the media coverage of their policies, as they assume that the public is highly influenced by the media. On the other hand, politicians, as well as other policy actors, all try to have their messages and policy activities in the media in order to communicate with each other and the public (Koch-Baumgarten and Voltmer, 2010; Van Aelst, 2014; Walgrave and Van Aelst, 2006). This process is “so intertwined that it is hardly possible to tell them apart” (Van Aelst and Vliegthart, 2013, p. 392). However, while some scholars observed that the influence of the media on the public policy

process is more dominant, others found that the influence of the public policy process on the media is stronger despite the fact that “the influence works both ways” (Van Aelst and Vliegenthart, 2014, p. 394). Against this background, in Section 3 we analyze the literature on the reciprocal relationship between the media and the transport policy process. We are especially interested to know which direction the influence has—is it from the transport policy process to the media or from the media to transport policy processes?

Both directions of influence—from the public policy process to the media and from the media to the public policy process—are conditional on various factors. Despite the fact that both influences do not run independently, for the ease of understanding we firstly explain how the influence of the public policy process on the media coverage is conditional, and then the other way around.

The influence of the public policy process on the media, namely the extent to which a public policy process is covered by the media, is conditional on the characteristics of the policy content (e.g., technical issues), policy events (e.g., routine politics or extraordinary policy events) and specific constellations of policy actors in the policy field concerned (e.g., a few conflicting prominent actors or numerous actors). Public policies where the characteristics of the policy content, events and actor constellations do not comply with news factors are not considered newsworthy and are ignored by the media (McQuail, 2010; Mencher, 2006). News factors are “criteria of news selection on which all journalists tend to agree” (Tresch, 2009, p. 70). For example, they include the prominence of the actors involved, the relevance of an issue, negativity, high level of conflict, geographical proximity, or the unexpectedness of an event (Mencher, 2006; Tuggle et al., 2004). The public policy process are filtered by the media according to these news factors and, thus, are not always reported, or are not fully covered. However, the media coverage of public policies may vary across media organizations as they may use slightly different news factors depending on their political slant, news tradition, editorial policies, reader profile or financial and organizational resources (Ardıç et al., 2015). For instance, the coverage may differ between popular and quality newspapers, as popular newspapers may select news based on news factors such as “negativity” or “personification” while quality ones may emphasize news factors like “controversy”, “relevance”, or “eliteness” more frequently because of differences in their commercial goals, reader profiles and editorial policies (Boukes and Vliegenthart, 2017). In the next section, based on these observations, we review the literature to explain how the transport policy process is covered in different types of media outlets.

The other direction of influence flows from the media to the public policy process. The media may have an impact on the public policy process in two ways: either rhetorically (impact on policy debate) or substantially (impact on actual policy decisions). In general, studies report strong media impact on a policy debate but rather weaker impact on actual policy measures (Van Aelst, 2014), so we discuss which types of influence are mentioned more frequently in the literature review results in the next section.

Whether or not the media has an influence on either a policy debate or actual policy decisions, the influence is contingent on the characteristics of the media input and the stages of the public policy process. Three characteristics of media input seem to determine the extent to which the media has an impact on the public policy process: the type of issue, the tone of the news and the type of media outlet (Van Aelst, 2014; Walgrave and Van Aelst, 2006). Regarding the type of the issue covered, it is argued that the media has more impact on a specific public policy when policy issues “without media would simply be not observable” (Walgrave and Van Aelst, 2006, p. 93). For example, the media coverage of foreign policy issues is expected to have a stronger impact on policy processes than that of domestic policy issues, as the media is usually the only information source of foreign policy issues for public and policy actors. Regarding the tone of the news, it is said that negative news leads to a stronger impact on public policies than positive news, as negative news urges political actors to give faster political reactions. Furthermore, not all types of media outlets have the same impact on the public policy process. It is speculated that newspapers have a stronger impact than TV news and “reliable and respected news outlets have more impact than marginal and dubious news sources” (Walgrave and Van Aelst, 2006, 93). Finally, Van Aelst and Vliegenthart (2013) show that newspapers with large audiences have stronger impacts.

Besides media input, media influence is considered to be conditional on the stages of the public policy process. The stages of the public policy process are the different phases of the process, such as “problem recognition, policy formulation, decision making, implementation, and evaluation” (Jann and Wegrich, 2007, p. 43). While some studies assume that media influence is observed during the initial phase of the public policy process when the policy problem is recognized, others show that the influence of the media is very likely to occur at other stages of the public policy process as well (Van Aelst, 2014). In the next section, we will explain in more detail the extent to which the media influence changes according to the different stages of a transport policy process and according to the characteristics of the media input: issue type, tone or type of media outlet.

Main Concerns of the Literature on the Media and Transport Policy

Table 1 lists all papers selected and summarizes their main findings. The columns of the table represent the following information about the papers, respectively: authors, transport policy issue and the country (and city) of investigation, and the main findings of the papers.

Reciprocal Relationship between the Media and the Transport Policy Process

Analyzing the road pricing policy process and its media coverage in the Netherlands, Ardıç et al. (2015) show that the relationship between the media and transport policy process is indeed reciprocal as suggested by Van Aelst (2014) and Van Aelst and Vliegenthart (2013). According to their findings, the influence from the road pricing policy process to the media seems to be more evident. That is

Table 1 Papers and main findings

<i>Papers</i>	<i>Transport policy issue</i>	<i>Country</i>	<i>Reciprocal relationship between the media and the transport policy process</i>	<i>Characteristics of the media coverage</i>	<i>Media influence on the transport policy process</i>
Connor and Wesolowski (2004)	Traffic accidents	The US	Not specified	Tone and issues: Restraint use is underreported; crashes involving drivers under the influence of alcohol and teen drivers are overrepresented; dramatic presentation with a victim/villain storyline Objectivity assessment: Not accurate (compared to official records) Media outlets: Minor differences among media outlets	Not specified
Beullens et al. (2008)	Traffic accidents	Belgium	Not specified	Tone and issues: Crashes are reported in a personalized and emotionalized manner; crashes involving young people are overrepresented; contributing factors to crashes are hardly mentioned	Not specified
Daniels et al. (2010)	Traffic accidents (motorcycle crashes)	Belgium	Not specified	Tone and issues: More serious injuries, crashes involving cars and happening on Saturdays and during the day are more frequently reported Objectivity assessment: Biased (compared to official records)	Not specified
De Ceunynck et al. (2015)	Traffic accidents	Belgium	Not specified	Tone and issues: More severe crashes, crashes involving young and female fatalities, bus or heavy goods vehicles, crashes happened on motorways, in Antwerp (compared to other provinces) and at the weekends are more frequently reported Objectivity assessment: Biased (compared to official records) Media outlets: No significant differences among media outlets	Not specified
Macmillan et al. (2016)	Traffic accidents (cycling safety and crashes)	The UK (London, Birmingham, Bristol, Cambridge)	Not specified	Tone and issues: Fatalities among females and younger individuals were more frequently reported; the media coverage of cyclist fatalities has increased tenfold, despite stability in the total number of cyclist fatalities in reality Media outlets: No significant differences among media outlets (only differences between newspapers in London and other cities)	Not specified
Vigar et al. (2011)	Transport policy package (inc. road pricing)	The UK (Manchester)	Not specified	Tone and issues: Mostly negative; charging measure is much more frequently reported than other measures Objectivity assessment: Not objective Media outlets: Considerable variation among media outlets; local media outlets are even-handed; the right wing press stressed the tax element more	Not specified

(continued)

Table 1 Papers and main findings (cont.)

<i>Papers</i>	<i>Transport policy issue</i>	<i>Country</i>	<i>Reciprocal relationship between the media and the transport policy process</i>	<i>Characteristics of the media coverage</i>	<i>Media influence on the transport policy process</i>
Ryley and Gjersoe (2006)	Road pricing policy	The UK (Edinburgh)	Not specified	Tone and issues: More negative than positive, becoming increasingly negative over time; scheme design, impact on business and congestion, fairness and equity were more frequently reported; impact on business and fairness were mostly reported negatively Objectivity assessment: Not objective Media outlets: One newspaper was more negative than the other; both newspapers changed tone over time	Not specified
Hamilton (2011)	Road pricing policy	Sweden (Stockholm)	Not specified	Tone and issues: Negative; operation cost of the system is frequently covered	Not specified
Ardıç et al. (2013)	Road pricing policy (two road pricing proposals)	The Netherlands	Not specified	Objectivity assessment: Not objective (compared to the average of media coverage) Media outlets: Two popular newspapers were negative and mixed, three quality newspapers were positive; privacy, impact on business sector and housing market were more frequently reported by popular ones, impact on the environment, road safety and car fleet, and labor market by quality ones	Not specified
Ardıç et al. (2015)	Road pricing policy (two road pricing proposals)	The Netherlands	The statements or actions of policy actors received media coverage, and the media coverage then stimulated the policy debate in each policy event	Tone and issues: Mainly positive; financial impact on households, impact on congestion, technical system and privacy issues were the most frequently reported; financial impact on households and privacy issues are the most negatively reported; the media coverage of two proposals have different characteristics.	The negative coverage by one newspaper influenced the policy debate; the negative coverage by one newspaper might have some impact on the removal of one proposal from the agenda; the influence of the media on the policy debate was rather indirect, meaning that policy actors mostly reacted to the messages from other policy actors in the media, rather than to the media coverage itself. The influence during policy stages: policy formulation and decision making
Nygrén et al. (2012)	Carbon-based car tax reform	Finland	Not specified	Tone and issues: Mainly positive; short-term impacts rather than long-term impacts are reported Objectivity assessment: Not objective	Not specified
Judge (2002)	Investment in motorway	Poland	Not specified	Tone and issues: Financial problems of the motorway program are more frequently reported than the environment impact and regional development issues	Not specified

(continued)

Table 1 Papers and main findings (*cont.*)

<i>Papers</i>	<i>Transport policy issue</i>	<i>Country</i>	<i>Reciprocal relationship between the media and the transport policy process</i>	<i>Characteristics of the media coverage</i>	<i>Media influence on the transport policy process</i>
Aldred et al. (2019)	Investments in cycling	The UK	Not specified	Tone and issues: Negative Objectivity assessment: Inaccurate (personal evaluation of interviewee)	Negative media coverage has hardly any impact on actual policy decisions (as stated by stakeholders) The influence during policy stages: problem recognition and policy formulation
Norley (2011)	Investments in public transportation	Australia (Sydney)	Not specified	Tone and issues: Positive, the media negatively covered delays and cancellations of public transport investments by the government	The positive media coverage and campaign of a newspaper have possibly some impact on actual policy decisions The influence during policy stages: problem recognition, policy formulation and decision making
Daniels et al. (2011)	Investments in public transportation	Australia (Sydney)	Not specified	Not specified	The positive campaign of a newspaper has possibly some impact on actual policy decisions The influence during policy stages: problem recognition, policy formulation and decision making
Wong and Fryxell (2004)	Fleet operations	China (Hong Kong)	Not specified	Not specified	Smaller firms are more strongly influenced by the media coverage (than bigger ones) with regard to adopting environmentally friendly fleet operations. The influence during policy stages: across all stages
Harding et al. (2016)	Auto-rickshaws	India	Not specified	Tone and issues: Largely negative, auto-rickshaws are covered as polluting and unsafe, a cause of congestion and the drivers as greedy	Negative media coverage (among other things) led to penalties and stringent regulations for auto-rickshaw drivers. The influence during policy stages: policy implementation and evaluation

to say, firstly the road pricing policy debate received some media coverage by attracting the media attention and then in reverse this media coverage influenced the policy debate. Furthermore, they analyzed that the media's impact on the policy debate was mainly indirect, meaning that policy actors reacted to statements of other actors in the media rather than to the media itself. But, this impact slightly varies according to the type of media outlet and tone of coverage.

Characteristics of the Media Coverage

Most studies in [Table 1](#) present research on characteristics of a media coverage and reflect on the extent to which the specific transport policy process has led to these characteristics in the media coverage. The studies examined four transport policy issues: traffic accidents, pricing policies (road pricing and car taxation), transport infrastructure investments (e.g., in road, public transportation, or cycling), and auto-rickshaw policy. Reviewing the findings of these studies in detail, we observe that the media coverage of these policy issues displays some similar characteristics, and also, that certain characteristics of a transport policy process seem to attract media attention more frequently.

Studies analyzing the media coverage of traffic accidents reported that traffic accidents involving young people ([Beullens et al., 2008](#); [Connor and Wesolowski, 2004](#); [De Ceunynck et al., 2015](#); [Macmillan et al., 2016](#)) or females ([De Ceunynck et al., 2015](#); [Macmillan et al., 2016](#)) and more severe crashes or serious injuries ([Daniels et al., 2010](#); [De Ceunynck et al., 2015](#)) were more frequently reported and were reported in a personalized and emotionalized manner ([Beullens et al., 2008](#); [Connor and Wesolowski, 2004](#)). [Connor and Wesolowski \(2004\)](#), [Daniels et al. \(2010\)](#) and [De Ceunynck et al. \(2015\)](#) compared these characteristics of the media coverage with those in official accident records and concluded that the media coverage was not objective,

in that some issues or events were over or underrepresented in the media. The more frequent media coverage of these characteristics seems to be related to their higher newsworthiness: scholars stated that crashes involving women fatalities were more frequently covered in the media because the low frequency of such crashes in reality made them more unexpected, and thus more newsworthy (De Ceunynck et al., 2015). Crashes involving teenagers were more newsworthy because they were more dramatic, compared to those involving adults (Connor and Wesolowski, 2004). An increase in the popularity of cycling in London made cycling accidents a more relevant issue and thus more newsworthy and raised the media's interest to cover cyclist fatalities, despite the fact that, in reality, no increase in cyclist fatalities could be observed. This caused a divergence in the media coverage of newspapers in London and other cities (Macmillan et al., 2016). But other than this, no difference in traffic accident coverage among media outlets was reported by other studies (see Table 1).

From the studies which examined the media coverage of road pricing policies and car taxation, two were conducted for British road pricing proposals, by Ryley and Gjersoe (2006) and Vigar et al. (2011), and one was for a Swedish proposal, by Hamilton (2011). They found that the road pricing policies were reported negatively by the media. On the other hand, the other two road pricing studies, one conducted for Dutch road pricing proposals by Ardiç et al. (2015) and one for a Finnish carbon-based car tax proposal by Nygrén et al. (2012), found that the media coverage for the proposals was positive. But all studies concluded that the media was not objective in its reporting of these proposals. As to the issues covered by the media, scheme design, the impact on business and congestion, and the financial impact on various households groups (equity/fairness) were more frequently reported during the Edinburgh road pricing policy process in the UK. Of these, the impact on business and various households groups had mostly negative coverage, as stated by Ryley and Gjersoe (2006). Likewise, in the Netherlands, Ardiç et al. (2015) reported that the financial impacts on various households groups, the impact on congestion, the technical system and privacy were the most frequently reported issues, and of these, the impact on various households groups and privacy were mostly negative.

Ardiç et al. (2015) explained that the characteristics of media coverage were the reflection of the Dutch road pricing policy process in as far as the specific policy debate and events and policy content complied with news factors. For instance, one pricing proposal during the 12 years of analysis of the Dutch policy debate on road pricing had more coverage than the other one because this one was more relevant, thus more newsworthy than the other one because of its comprehensive system design which was expected to influence the financial situation and mobility behavior of the whole population. Or, the privacy issue was almost always negatively covered by the media during the 12 years of the analysis period, except during one policy event in which a technical report was published. The findings of the report were positive about the privacy aspects of the proposal and most of the prominent actors reacted positively to these findings. An extraordinary event (the publication of this report) and the reactions of prominent individuals (political leaders) made these positive events and reactions newsworthy for the media and thus led to the positive media coverage of this issue.

Furthermore, Ardiç et al. (2013), Ryley and Gjersoe (2006), and Vigar et al. (2011) indicated that the characteristics of road pricing media coverage (the tone and issues reported) varied across different media outlets. Ardiç et al. (2013) observed the differentiation between popular and quality newspapers: two popular newspapers were usually negative and mixed, three quality newspapers were usually positive over the 12 years when the policy process was analyzed. Yet, why such differences occur between quality and popular newspapers (e.g., editorial policies, reader profile or commercial concerns), or what new factors are relatively more important to each newspaper, is not known. Ardiç et al. (2013), however, mentioned a possible editorial influence on the tone of one newspaper's coverage.

The remaining papers, which address the extent to which the transport policy process is covered by the media, are about four different policy issues from four different countries. Aldred et al. (2019) reported that investments in cycling in the UK had negative and inaccurate coverage, according to the opinions of stakeholders. Examining media coverage of a Polish motorway investment program, Judge (2002) found that the media reported the financial problems of motorway programs more frequently than the environmental impact and regional development issues. It seems that "the urgency of domestic financing issues, ... the dominance of external funders" on the Polish public agenda made the financing aspect of the program more relevant, and therefore more newsworthy for the media. Norley (2011), on the other hand, indicated that the media coverage of investment in public transport was positive in Australia. In addition to that, a newspaper even started a campaign to promote public transport on the public agenda (Norley, 2011). Therefore, editorial policies seemed to play a role in the positive coverage of public transport in Australia. Finally, Harding et al. (2016) analyzed the media coverage of auto-rickshaws in India and found that media coverage was largely negative and auto-rickshaws were covered as polluting and unsafe, a cause of congestion and the drivers as greedy. Such media coverage was very likely to be a reflection of "considerable criticism from public, ... and policy makers" about auto-rickshaws, as stated by Harding et al. (2016, p.143). Such opposition from the public and policy makers should have increased the newsworthiness of these negative aspects of auto-rickshaws and, thus, amounted to media coverage of these aspects.

Media Influence on the Transport Policy Process

Not many of the papers in Table 1 investigated the influence of the media on the transport policy process. Only the study by Ardiç et al. (2015) analyzed the influence of media coverage on the transport policy debate, four other studies considered only the media's influence on actual policy decisions. Comparing media coverage of road pricing policies and parliamentary debates over time, Ardiç et al. (2015) found that the media coverage indeed influenced the parliamentary debate, but rather indirectly. That is to say, parliamentarians reacted, not to newspapers, but to the statements made by other parliamentarians and policy actors covered by the news. This indicates that, in this case, the media mainly acted as a communication platform. The findings of other studies were

related to the influence of media on actual policy decisions. Aldred et al. (2019) argued that negative media coverage had hardly any impact on actual policy decisions regarding investments in cycling in the UK. Daniels et al. (2011), Harding et al. (2016), Norley (2011), and Wong and Fryxell (2004), on the other hand, claimed that the media possibly had some impact on actual policy decisions. The analyses of Wong and Fryxell (2004) and Aldred et al. (2019) are based on the views of stakeholders, but the empirical evidence in the studies of Daniels et al. (2011), Harding et al. (2016), and Norley (2011) is not very clear.

According to Ardiç et al. (2015) and Norley (2011), some newspapers are relatively more influential or play a more active role (like other policy actors) in the policy process. When analyzing references made to one popular newspaper during parliamentary meetings, Ardiç et al. (2015) pointed out that the negative coverage of this newspaper was likely to be one of the factors which played a role in the policy decision to abandon one of the road pricing proposals. In addition, the analysis of Ardiç et al. (2015) proved that this newspaper had a stronger impact on the policy debate than other newspapers. This stronger impact could be because of its wider readership or its negative coverage about the road pricing proposal, as Van Aelst and Vliegenthart (2013), Walgrave and Van Aelst (2006) stated. Similarly, Norley (2011) stated that the editorial office of one newspaper possibly played a role in transport policy planning by organizing a campaign to promote public transportation in Australia.

Finally, the studies mentioned in the previous paragraphs reported that media influence was observed across almost all stages of the transport policy process, with the policy recognition and policy formulation stages being more profound. They do not support the findings of studies which argue that media influence is limited to the policy recognition stages of a policy process (see Van Aelst, 2014).

Conclusion

This article aimed to explore the role of the media in transport planning and the transport policy process. To achieve this aim, we scrutinized the relationship between the media and the transport policy process, based on findings in existing literature and we used theoretical perspectives developed in the field of public policy and the media. Our analysis indicated that this relationship is reciprocal. That is to say that the influence of the media on the transport policy process, and its reverse, the influence of the transport policy process on the media, both exist. The current state of research in the field of transport policy presents ample evidence that the characteristics of the specific transport policy process (related to policy content, events, and actors) are reflected on the media coverage to some extent, whereas limited evidence is found regarding the influence of the media on the transport policy process, and the circumstances under which such influence is observed.

The results of our review support the research findings of public policy presented in Section 2 in a way that certain characteristics of a transport policy process attract media attention more frequently. Unexpected, extraordinary or dramatic events, speeches by prominent actors (both negative and positive), and relevant issues concerning or influencing many people's lives during the transport policy process are likely to be considered newsworthy by the media and receive media coverage. Most studies reviewed made an inference to the extent to which the media was objective in its reporting of the transport policy process and interestingly, they all concluded that the media did not report the policy process objectively. But, their findings in this regard (except one about traffic accidents) do not have a strong empirical basis as they did not use an independent measure of reality (media input, namely transport policy process) to compare to the media coverage in their measurement of media objectivity. "Reality" is not clearly defined in the studies of Nygrén et al. (2012), Ryley and Gjersoe (2006), and Vigar et al. (2011). Ardiç et al. (2013) consider the average of five newspapers as "reality" and compare each newspaper's coverage to this so-called reality to measure their objectivity. However, we note that it is not easy to find any decent measurement for "reality" for public policy debate and process (as it is for traffic accidents) to compare this to media coverage in order to evaluate the objectivity of media reporting (see detailed discussion about measurement of objectivity (McQuail, 1999)). No difference is found among newspapers in terms of the media coverage of traffic accidents, but with respect to road pricing policies, studies reported considerable differences among newspapers. It is likely that, because of the politicized nature of road pricing policy processes during the policy formulation period, as stated by Ardiç et al. (2013), Ryley and Gjersoe (2006), and Vigar et al. (2011), political slants, reader profile and the editorial policies of newspapers become more evident in the way of reporting and so they diverged their coverage accordingly.

With respect to the influence of the media on the transport policy process, Ardiç et al. (2015) provided empirical evidence regarding the influence of the media on the road pricing policy debate. Their findings imply that the media mainly acted as a kind of communication platform during the policy process. Namely, parliamentarians reacted, not to newspapers, but to the statements of other parliamentarians and policy actors covered by the news. The rest of the studies discuss whether the media influenced actual policy decisions. But, they do not seem to present very strong empirical evidence regarding the influence of media on actual policy decisions. Nevertheless, it should be admitted that, methodologically, it is very difficult to distil the influence of the media on actual policy decisions because public policy making is very complex and numerous factors play a role in actual policy decisions. Regarding the contingency of media influence on the type of media outlet, it is interesting that some newspapers seem to be relatively more influential, or play a more active role (like other policy actors) in the policy process. One newspaper in the Dutch road pricing policy process and the one in policy process regarding public transport in Australia influenced policy debate (possibly actual policy decisions) played an active role. Finally, media influence was observed across almost all stages of the transport policy process, but, in the studies that were reviewed, it is more often observed during the policy recognition and policy formulation stages.

To sum up, this article has shown that the media and the transport policy process influence each other reciprocally, but this influence is conditional on various factors. Most strikingly, research on this topic seems to be in its infancy. More research and more

specific case studies are needed to better understand the influence of the media on the transport policy process. Furthermore, all studies in this review involve only one country. Crosscountry differences in terms of political and media systems might give more insight into the relationship between the media and the public policy process. Thus, it might be useful to examine the role of media and the transport policy process by comparing cases from different countries in one study.

Defining and Characterizing the Travel Plan

Travel Plans have had a variety of names (Green Commuter Plan, Green Transport Plan, Sustainable Travel Plan, Mobility Management among others) and have been defined in a number of ways. These include:

- “A travel plan sets out to combat over-dependency on cars by boosting all the possible alternatives to single occupancy car use It cannot only benefit the environment but can produce financial benefits and productivity improvements.” (NBTN/ Department for Transport – *The Essential Guide to Travel Planning* 2008).
- “Travel planning is an effective business management tool which can be used to generate cost savings, lending companies a competitive advantage, and which has additional benefits for the environment and the health of employees.” (Transport for London, - *Business on the move*, 2005).
- “A package of measures to meet the needs of individual site(s) aimed at promoting greener, cleaner travel choices and reducing reliance on the car. It involves the development of a set of mechanisms, initiatives and targets that together can enable an organisation to reduce the impact of travel and transport on the environment whilst also bringing a number of benefits to the organisation and to staff.” (Energy Efficiency Best Practice Programme, 2001)

The differences in definition often reflect the perspective from which Travel Plans are considered. A city or transport planning authority will emphasize the transport system and environmental benefits that a Travel Plan might deliver; a business organization would take a business efficiency perspective and a funder of an organization (e.g., an education authority funding schools) might take a more regulatory/compliance approach.

In synthesizing meaning from a range of definitions, [Enoch \(2012\)](#) noted that the common themes emerging from these definitions are:

- Travel Plans are not an instrument themselves, but a delivery mechanism or strategy for other mostly transport-focused measures.
- Travel Plans are delivered by an additional “agent” that is not a part of the “traditional” transport policy institutional structure. This agent may be an employer, a school, a shopping center or any organization with responsibility for a site that generates traffic impacts.
- Travel Plans are initiated in two ways: either by the organization concerned or by a government body.
- Travel Plans seek to deliver transport and related benefits to the community as well as some direct organizational benefits to the participating “delivery agents.”
- Travel Plans are to some extent “site-specific,” that is tailored to the specific contextual circumstances.
- Travel Plans to some extent deliver a package or a strategy of a variety of transport instruments.

[Enoch \(2012\)](#) uses a definition that stems from these points, in that Travel Plans are:

“a mechanism for delivering a package of transport measures targeted at a specific site by an agent with a strong relationship with the local transport users to deliver transport and wider goals to the organisation and society as a whole”

(Enoch 2012, p.58)

In practice Travel Plans have been applied to a number of sectors, including schools ([Baslington, 2008](#)), residences ([De Gruyter et al., 2015](#)), visitor attractions ([Guiver and Stanford, 2014](#)) and hospitals ([TfL, 2006](#); [NHS 2006](#)), as well as retail, events and transport interchanges, though they are mostly associated with employers ([Roby, 2010](#)), and with the commute trip in particular. This chapter examines the evolution of the Travel Plan in its three stages so far, namely: emergence, stagnation, and transformation.

Emergence

For many years some employers have helped staff travel to work. Factories in remote locations might provide works buses for staff and often special transport arrangements are made for late-night shift workers. The Travel Plan concept—that employers and organizations should take responsibility to manage how staff, customers, and visitors travel to their site in response to wider public policy reasons—is a more recent development. The first initiative of this sort can be traced back to the 1940s, when as part of the war effort to conserve fuel, Boeing in Seattle introduced a car lift sharing scheme and a promotional poster of the time declared “When you ride ALONE, you ride with Hitler!”. After the war ended, the need to conserve fuel ceased and so too did car share schemes. Another external jolt led to their return, when the 1973 Yom Kippur War and the overthrow of the Shah of Iran in 1979 led large companies such as Amoco in Houston, 3M in Minneapolis-St Paul and Aerospace Corporation in Los Angeles to introduce measures to help their staff get to work (Shreffler, 1986).

The first environmental requirements for employers to manage the travel of their staff came as part of Californian air-quality legislation in the 1970s. The Dutch adopted Travel Plan type measures in the 1980s and local authorities in the United Kingdom (notably Nottingham City Council) began promoting “green commuter plans” in the early 1990s. The promotion of Travel Plans became UK Government policy from 1997, with workplace and school Travel Plans featuring in the 1998 and 2004 transport policy White Papers (DETR, 1998 and DfT, 2004). Travel Plans have also been adopted in other countries throughout Europe (EPOMM, 2013), as well as in Australia, New Zealand, Canada, and Japan (Enoch, 2012).

Motivations for Promoting or Adopting Travel Plans

A distinction from conventional transport policy is that Travel Plans are not primarily implemented by public bodies through planning, regulations, or infrastructure investments (e.g., building roads, cycleways, or metro systems). Instead, the implementation and management of a Travel Plan is by the organization whose site or operations generates traffic impacts. The varying emphases in the Travel Plan definitions above represent this shift in how public policy engages with such organizations. A crucial aspect for Travel Plan success is how such engagement is achieved and what motivates organizations to adopt and maintain a Travel Plan.

The involvement of organizations whose operations generate traffic impacts is both a strength and a weakness of the Travel Plan approach. The main weakness is that the vast majority of employers and other institutions do not see solving transport problems as their responsibility. To date, rather than adopting an integrated management approach, employers have tended to treat transport matters as either separate self-contained issues or a matter that is largely outside their control and not their responsibility. These issues have included:

- Road congestion affecting delivery reliability and costs (as well as staff punctuality)
- Congestion of on-site parking
- Transport-related planning conditions required for site development
- Changes to the tax treatment of transport benefits in the remuneration package (company cars, mileage allowances, etc.) and other transport-related human resource issues
- Transport and company environmental policies (including environmental requirements of export markets and other supply chain pressures)
- Transport effects upon brand image and public relations
- Transport impacts upon company quality initiatives.
- Meeting Corporate Social Responsibility goals, climbing “green league tables,” corporate image
- Recruitment and retention

As in all good management practice, it is crucial not to treat these seemingly disparate issues in isolation: this leads to ad hoc “fire fighting” that is costly and ineffective. The key to a cost-effective and successful approach is to recognize that organizations are dealing with a series of challenges and opportunities stemming from changes in the transport environment. A strategic, integrated business approach is needed, and this is where Travel Plans come into their own.

Nevertheless, companies generally consider Travel Plans only when some other pressing reason forces them to do so (Rye, 2002). In some cases, a Travel Plan can arise from a crisis of on-site parking congestion, or a perception that a company’s transport problems are harming its business image. For example, it could be embarrassing to a university that teaches environmental management if it could not show that it practices what it preaches by having an effective Travel Plan. However, in the majority of cases the most pressing reason arises when a company wishes to move to a new site or expand its existing site, and the local authority forces it, through a condition of planning consent, to manage the ways in which employees or customers travel. This approach is commonly used in the United Kingdom, Australia, and the United States, and is often tied to the principle that new developments generate an additional burden on surrounding infrastructure and services that needs to be mitigated (De Gruyter et al., 2018).

Outside of Travel Plans being required for new developments, in some places they were introduced as a measure for all employment sites in a city. This approach was first trialed in 1985 in several districts of California to combat air pollution, with the concept transferred to the Netherlands in 1989 following a study tour of Dutch policy makers looking to solutions for worsening traffic congestion (Hoogma, 2006). For some public sector organizations, a Travel Plan might be required directly by Government or as a condition of finance.

When consistently applied, Travel Plans can cut car use by worthwhile amounts. The best employer travel plans in the United Kingdom secured a reduction in car use of between 10% and 20%, while some feel that up to 30% is a possibility (Cairns et al., 2004). In the United States, where mandatory Travel Plans have been in use, in several cases a 30% cut in car use has been achieved.

Stagnation

Despite the potential promised by the concept, Travel Plans have never really established themselves as a mainstream part of transport policy. Despite the many apparent benefits afforded, in most locations Travel Plans have remained a relatively niche concern, with the overall impact on the transport network being correspondingly marginal. Thus, Rye (2002) concludes that, although there is clear evidence that Travel Plans have an effect at the site level, their potential for a system-wide effect was unrealized. He estimated that the contribution of Travel Plans to congestion reduction at the UK level to be less than 1% at the time of publication (2002), and anecdotal evidence suggests that nothing significant has occurred since that might have changed this to any degree.

Barriers to Travel Plan Take Up

Within organizations, Travel Plans were easily marginalized and discarded if they conflicted with other priorities. This particularly applied to where Travel Plans had been a regulatory imposition (planning or sector requirement), which tended to lead to a “minimum cost for compliance” approach. If the specification was simply to produce a Travel Plan, then the document was logged and no further actions taken to implement or maintain it. Even if the specification required the Travel Plan to be implemented with certain measures or to achieve a car use reduction target, it might fall into disuse when the regulatory pressure eased. Around the 2008 financial crisis and subsequent recession, many Travel Plans were simply discarded.

An in-depth study of 25 Travel Plans (Roby 2008), explored this issue, noting that all were originally driven by external factors, such as a planning condition or government directive. Eventually, about a third started to identify internal benefits of the Travel Plan, particularly reducing car parking costs, but also a positive impact on recruitment and retention. The majority, however, remained motivated by external requirements and had not developed an internal rationale for their existence.

Even if internal benefits could be identified, these were often too small to justify much resource being devoted to a Travel Plan or the benefits could not be financially captured. A key structural point is that the main benefits often fall outside the department that funds the Travel Plan. It is quite usual for a Travel Plan to be the responsibility of a Facilities or Estates department. This is because of their institutional responsibilities and they link to a local authority or the site management side of their funding body – the organizations that impose a Travel Plan requirement. The cost of running a Travel Plan can be offset by reductions in other expenditure within a Facilities department’s budget; hence it is not surprising that reducing car parking costs was the main internal benefit identified in Roby (2008). However, cross-departmental costs and benefits are more difficult to manage. Staff recruitment and retention is the responsibility of personnel, and they might be reluctant to transfer monies to facilities even if the Travel Plan does provide them with real benefits.

Issues that produce impacts across a business need to move up the management hierarchy, but, as noted by Enoch (2012) Travel Planning largely became “ghettoised” - a function undertaken by junior staff in the lower echelons of a Facilities department. In a very few cases, Travel Plans (or components of Travel Plans) came to be recognized of sufficient importance that they were supported by the managerial board who allocated them strategic resources. This was so for a number of university Travel Plans. One example is the University of Hertfordshire, which has developed a bus network serving its campuses and the surrounding areas. Cranfield University and the University of Falmouth are among others that also run their own bus services. The reason these are important for these universities is that they link into an issue of strategic importance—student recruitment and retention. The bus services provide a much-valued benefit to fee-paying students who increasingly expect good accommodation, social facilities and access. This Travel Plan measure has become of importance to student recruitment. The bus routes are public services and have developed to become profitable, so are doubly valued as now being a profit center as well as contributing to student recruitment and retention.

A second key factor in the stagnation and decline of Travel Plans has been that they were part of a demand management strategy for transport policy that came to be abandoned. Furthermore, Travel Plans were not just a demand management initiative, but they were something that involved a different means of implementation. Traditional transport policy is a civil-engineering focused area, built around state infrastructure projects funded by general taxation. A shift to demand management transport measures has largely retained this regime approach; instead of infrastructure projects for roads, the same approach and skills are used for infrastructure projects for public transport and cycle ways etc. But Travel Planning involves a different approach and skill set. It is about sustaining initiatives, not one-off civil engineering project actions; it is about building partnerships, consulting, educating and empowering users, implemented by a dispersed range of stakeholders—the role of the state (particularly local authorities) is significantly different. It is more like a management process than “traditional” transport engineering.

Enoch (2012) detailed the institutional barriers for Travel Planning in more detail, noting that this existed within Government and within organizations and was a product of how Travel Planning itself had emerged. Broadly, he concluded that Travel Plans had become vulnerable because they do not map onto the structures of the organizations in which they take place, nor the organizational structures and operating regimes of Government. The skills and culture clash between travel planners and the contexts in which they operate resulted in their stagnation and decline.

Furthermore, following the 2008 recession the ethos of transport policy shifted away from the demand management approach in which Travel Plans were rooted. In the UK context, after an initial flirtation in 2010 with austerity across the board, in 2016 the focus of the Conservative Government for transport shifted toward investing in major infrastructure projects to generate economic growth, albeit with a significant emphasis on public transport projects, such as London Crossrail and the High Speed 2 rail project. Major road expansions also took place including the use of “Smart” motorways to enlarge existing motorway capacity, an approach that did not require any engagement at a detailed level with employers or other organizations. To date, this emphasis on infrastructure expansion has not been viewed as incompatible with the growing climate change agenda as that was being addressed by measures that were compatible with the existing policy implementation approach. This was through traditional fiscal and regulatory measures to promote a fuel shift to electric vehicles combined with the decarbonisation of electricity generation. Transport policy reverted to what it was able to do—civil engineering projects and a policy regression to an emphasis on infrastructure expansion. In such a policy climate, Travel Plans became an irrelevance.

Transformation

Yet policy contexts rarely stand still for long, and circumstances have continued to evolve regarding Travel Plan services, although often not labeled or presented under the term “Travel Plan.” There has been a dramatic change in the ecosystem of organizations providing “plug and play” Travel Plan services for employers and other organizations, many of which have come from the digital economy. These range from global players such as Uber to much smaller enterprises like Vectare, which provides niche consultancy software and managed transport solutions to schools seeking to deliver safer and more efficient transport options to pupils. Another example is the sustainable transport consultancy Go Travel Solutions.

In addition, a whole suite of data generating and analytics companies such as BlockDox, Vivacity and Elephant Wi-Fi have moved to operate in the transport space, making it much more straightforward for organizations to fully understand and proactively influence the travel patterns of their employees, students, patients, and visitors at an ever diminishing cost and effort. Ten years ago, such data gathering and analysis was ad hoc, expensive, and tied up staff resources. Now travel information is found in the standard portfolio of data gathering and analytics service companies.

Another (related) change has been the rise of corporate “wellness” programs, as supported by Government policy announcements such as the work, health, and disability green paper: *Improving Lives* (DWP and DHSC, 2017), whereby companies support and encourage employees to look after their health by, for example, stopping smoking.

A further strand stimulating the return of Travel Plan type actions are two attitudinal shifts. First has been a steady increase in the “sharing economy.” This is typified by the highly successful Airbnb accommodation service, but there are transport examples where people share their car journeys with others in return for a charge and sharing material possessions such as cars or bikes through a Digital Service Platform (see www.earthshare.org). Second, there have been signs that the public is becoming much more supportive of policies aimed at addressing air quality, congestion, and climate change that require actions traditional transport policies cannot deliver. Hence, many cities around the world have recently introduced regulations to limit access to polluting vehicles into urban centers such as the Crit’Air Low Emission Zone scheme in France, and License Plate Restriction policies throughout Latin America and China (Ramos et al., 2017), which suggests that there may be also scope for Travel Plans focused on addressing these agendas.

Subsequent to these however, three key events during the first few months of 2020 have once again fundamentally changed many of the core assumptions underpinning transport policy. First, there was the ruling, on 27th February in the UK Court of Appeal in London that the Heathrow third runway could not go ahead because it is not consistent with the Paris Agreement on Climate Change (Carrington, 2020). Second, and related to this was the release of the Decarbonising transport: Setting the Agenda White Paper by the Department for Transport on 26th March (DfT, 2020), which committed the UK Government to prioritizing active travel and public transport. Interestingly, while it does not refer to Travel Plans explicitly, it does acknowledge the importance of “place-based solutions” as one of six strategic priorities which could potentially be viewed at a more neighborhood scale than the local authority level envisaged currently (pp. 7).

Third, and perhaps most significant are the ramifications of the global Corona virus pandemic set to significantly impact on how people travel in future (Enoch and Warren, 2020), and also on the financial ability of the Government to continue to spend on infrastructure improvements once the crisis is over. In addition, it is clear that one key element in ensuring the effectiveness of Government policy actions, around social distancing measures in particular, is to have employers “on side.” Indeed, one oft-cited reason for people traveling in spite of Government instructions not to during late March 2020 was that they were required to do so by their employers to keep their job (McCrum et al., 2020). This realization, that engagement with the factors behind the generator of traffic is needed and not a response to them, may well have been one reason for a guidance for employers and businesses on the corona virus note being issued by Government in early April 2020, which pointed out the need to encourage working from home policies as its first piece of advice—essentially a Travel Plan measure (DEBIS and PHE, 2020).

Taken together, these technological, attitudinal, and policy drivers present a situation in which the concept of the Travel Plan could well re-emerge, but likely in a much less structured and visible incarnation than when they were first adopted. Hence, many (perhaps most) organizations may well find themselves implementing one or more of the “plug-and-play” tools provided by a growing emergent digital cottage industry comprising suppliers of business-facing (travel-impacting) solutions without ever realizing that they are engaged in putting a Travel Plan in place. Related to this shift toward “shadow” Travel Plans among some organizations has been a parallel downplaying of the traditional Travel Plan concept within Government, as highlighted in the Decarbonising Transport report mentioned earlier. Yet in the final analysis, this “invisibility” may actually prove to be a blessing, as

long as the whole suite of supporting information, fiscal, and regulatory policies across Government around managing car use and promoting active travel and public transport use are put in place to encourage organizations to make the “right choices” during the course of their day-to-day operations.

Introduction: The Concept

Sustainable Urban Mobility is today a significant concern from almost all cities in the developed and developing world. For a long time it was exclusively focused on the movement of people, but in the last years a growing consensus was established that urban mobility must encompass the sustainable movement of freight, without which living in urban areas is impossible. It is thus essential to understand how freight distribution integrates within the transport system and look at Sustainable Urban Logistic Plans (SULP) as a mean to manage urban logistics.

At the EU level, the President of the European Commission Ursula von der Leyen announced the European Green Deal (European Commission, 2019), within the priorities for 2019–24. This represents a growth strategy aiming to transform EU into a prosperous and equitable society, with efficient utilization of resources and competitive, that aims to reach 2050 with zero emissions and with economic growth decouples from resource utilization. A set of measures and objectives have been set, namely, the transition to sustainable and intelligent mobility, leading the transition to a clean and circular economy.

Since the 80s, several research projects were developed addressing many aspects of the organization of freight distribution in the urban environment. It is worth highlighting from the outset the SULP planning cycle developed by the NOVELOG project (Fig. 1) that identifies the six steps of the planning cycle for urban logistics, divided into two main phases, the preparation and the goal setting.

Home deliveries are a concept covering the movements encompassing the distribution of freight for household consumption. The citizens often initiate home deliveries process ordering their needed goods (e.g., from supermarkets or other retail shops). Other cases, the supplier can begin the process. Home deliveries are one of the most critical segments of urban freight distribution, currently growing in direct relation with the development of the digital world and Internet shopping, and one of the trends with high impact on freight traffic in urban areas. Eurostat reports that “60% of people in the EU aged 16–74 shopped on-line during the year prior to the 2019 survey, compared with 56% in the 2018 survey. Compared with 2009, the share of on-line shoppers had almost doubled from 32%” (European Commission, 2020).

Home deliveries result from consumers buying physical goods (not services) from on-line stores on the Internet (i.e. business to consumer or B2C). It is often confused with e-commerce, which is a broader concept entailing any commercial transaction between organizations and persons. Besides B2C, some websites (e.g., eBay) promote the trade of second-hand goods or homemade products, between consumers (consumer to consumer), also included in home deliveries.

Factors Influencing Home Deliveries

It is crucial to understand which factors influence home deliveries. For this analysis, we use the PESTEL methodology, which acronym represents the domains of analysis, being: Political; Economic; Social; Technological; Environmental; Legal, and regulatory.

Political Factors

Transport and logistics is a sector with high contribution to greenhouse gas emissions as it uses mostly fossil fuels (ref year 2020). The EU Commissioner Velez (European Commission, 2018) puts forward the priority area for the EU, being:

- Promoting the adoption of clean vehicles and alternative fuels.
- Increase the modal share of the most sustainable modes in the transport chain.

Figure 1 SULP planning cycle. Source: NOVELOG.

There is a strong political interest in shifting freight mobility to more sustainable solutions, and this is a driver for the organization of home deliveries within broader sustainable plans. The SULP – Sustainable Urban Logistic Plans have a recent history. The first EU project dedicated to the development of SULP dates from 2012 to 2015 (ENCLOSE), and more information is available in TRIMIS portal.

Economic Factors

Freight transport, of any type, is closely related to the economic activity of the area. In periods of economic growth, the population increases its available income and, consequently, the consumption of goods and services increases and, in turn, freight transport demand increases. The opposite is also true when economic contraction occurs. The World Economic Forum reports that from 2014 to 2019 e-commerce tripled (WEF, 2020), and no figures are available for Home Deliveries as defined above. However, the graphic presented in Fig. 2 presents the evolution of e-commerce items considering two dimensions, for the years 2017 and 2019: vertical axe reflects the quantity of items researched on-line; and, the horizontal axe reflects the percentage of on-line shopping. The increase of online shopping significantly fostered by digitalization leads to an increase of freight distribution not only in the direct delivery but also in returns due to any misfitting reason.

Main delivery points are: households, convenience stores, workplaces, and lockers. However, the real impact of urban logistics dynamic is yet to be accurately calculated, although we know that the type of vehicle used in the distribution is critical for the level of emissions produced. Besides, the more home deliveries increase more situations of potential conflict and accidents accrue with pedestrians and other vehicles, as well as a significant contribution to congestion.

Social Factors

European Union has a high urbanization rate. According to Eurostat I in 2014, 380 million inhabitants lived in urban areas. There is a clear increasing trend, and the projection for 2050 is to have between 450 and 550 million inhabitants (JRC, 2019).

Moreover, there is an intensive ageing process in our societies. Consumption increases with increased urbanization and consumption patterns change with ageing population. In both cases, home deliveries will increase.

Figure 2 Increase of e-commerce from 2017 to 2019. Public source: WEF.

The speed of living is also changing, and this is made evident in consumption patterns of the new generations. The industry tries to match the needs of society and respective changes. During key informant interviews the following examples were reported as being the reality of 2019: Zara (from Inditex) changes clothes portfolio every 4 weeks. All products are ephemeral; Amazon implemented deliveries in 24–48 h, and delivers in 1 hour in several cities; while, Farfetch delivers clothes anywhere in the world in 24–48 h.

Technological Factors

Technological issues have been a driver for the development of new services for home deliveries. The domains where more intense impact is detected are: information systems; vehicle technology; infrastructure technology; operational management; and, monitoring.

Technology enables the sophistication of home delivery services, in particular in the communication with clients building a trusting relationship with the service.

Environmental Factors

The environmental domain is critical. Transport is responsible for 27% of greenhouse emissions and equivalent consumption of nonrenewable energy (EEA, 2019). Urban logistics is responsible for about 23% of carbon emissions in UE. No specific information exists for home delivery, but the trend is to maintain pressure over the whole urban logistic segments for the reduction of negative externalities.

Internalization of externalities implies an increase of direct operational costs for the transport operator. Besides, the global complexity of the urban system and existing restrictions (e.g., traffic, accesses, parking) provides large room for improvement in efficiency, although incentives are required to succeed.

Legal and Regulatory Factors

Intervention of public entities in urban logistics in general and, in particular, home deliveries, is recent. Regulation is still in an infant phase, but both internal (supported by the agents) and external costs (supported by the society) are drivers for change. It is recognized that important regulatory gaps exist, made evident namely through the growing pollutant emissions in urban area or the contribution to congestion with additional vehicle kilometers done by the deliveries whenever a lack of infrastructure to loading and unloading exists. From the operators perspective there is also a reduced efficiency of services and logistic operations whenever vehicles are in operation with a reduced load factor, or with overlapping routes, or forced to long periods of loading and unloading.

Despite being a sector primarily dominated by private entrepreneurs there are still many measures that can be implemented by the public authorities that can contribute to improve the overall performance of the sector. These measures should consider both the internal costs (beared by the operators) and the external costs (beared by the society).

Typology of Home Deliveries

Business models for home deliveries are blooming since 2010. Many innovative models have been developed. Papoutsis and Nathanail (2018) provide an extensive list of alternative measure for home deliveries, with identification of the research project where more detailed information can be found regarding cases where each measure was implemented.

We highlight here some of the most relevant measures, although we insist that reading the reference provides added value to the reader.

The most relevant measures for home deliveries are:

<i>Measure</i>	<i>Type of measure</i>	<i>Location of implementation</i>	<i>Research project for more details</i>
Pooling of inner city freight delivery	Cooperation	Aachen	C-LIEGE
Electric delivery vehicles for final deliveries	Vehicle Technology	Paris	TURBLOG
New delivery service exclusively using “cargo cycles” or electrically powered tricycles	Infrastructure and vehicle technology	Paris	TURBLOG
Pack Stations 24/7 (e-commerce) with lockers	New business model	Szczecin	C-LIEGE
Private logistic services, Dabbawala	New business model	Mumbai	TURBLOG
Time windows for deliveries	Regulatory	Bristol	START
Lockers	Technology and regulatory	Paris	Technology and regulatory

Home Deliveries Within the Broader Urban Logistics Framework

It is rare to find examples of integrated approaches to regulation and strategic planning in urban logistics the most common situation is to implement isolated measures with specific objectives. An integrated approach would imply tackling all the aspects that are upstream and downstream the act of freight distribution (see Fig. 1) and understand the effects that those aspects have in the performance of urban logistics as a whole.

The study of urban freight tasks is complex and heterogeneous, as it is strongly related with many other aspects of the urban system, such as: urban passenger system, land use, regional development, employment, etc. When considering urban freight planning it is necessary to devote some effort towards understanding its integration within urban mobility planning. For example, considering metropolitan areas urban freight must be considered in the master plan and a roadmap should be developed with guidelines for the development of business and commerce, in particular for home deliveries which have often a long supply chain that must be integrated without frictions between the different transport modes used (Reis and Macário, 2019). In a small town, access and parking regulations can be useful but it is insufficient, so innovative measures have to be considered to reduce the flow of vehicles associated with home deliveries. Some of the good practices that have provided good results are the establishment of pick-up points, or intelligent lockers, etc., Should not be forgotten that each city has its one life cycle and the respective pace of development which represents an indication of the city capacity to change.

In what concerns urban freight we can find three stages of development (Macário, 2013) for every city: the first stage, the restriction stage, characterized by urban areas that show no urban logistic policies and where regulation is only restrictive; the second stage, the new practices stage, when policy documents start being published and opening innovation avenues; the third stage, policy and practice stage, when cities start organizing their SULP. The following table identifies macro measures where home deliveries are included (Macário, 2013).

Table 1 Measures for different stages of development with relevancy for home deliveries

<i>Urban stage of development</i>	<i>Type of measure</i>	<i>Examples</i>
Restriction stage	Access restriction measures	Access restrictions according to vehicle characteristics (weight and volume)
Restriction stage	Legislative and organizational measures	Cooperative logistic systems, encouraging night deliveries, public private partnerships, intermediate delivery depots
New practice stage	Territorial management	Creation of loading and unloading areas, of load transfers, mini logistics platforms, and drop-off points
New practice stage	Technological measures	GPS, track and tracing systems, route planning software, intelligent transport systems, adoption of nonpolluting vehicles and vehicles adapted to urban characteristics (size and propulsion)
Policy and practice	Infrastructural measures	Implementation of urban distribution centers and peripheral storage facilities
Policy and practice stage	Policy oriented	Identification of logistic profiles, development of Master plans, recognizing the need for different solutions for different market segments

Rationalization of the freight distribution process (from the economic, spatial, and temporal perspectives) is required. This means reducing the flow of goods yet keeping the adequate level of distribution to satisfy consumer's needs.

Introduction

What should be the transport policy with respect to safety and security? If we start by looking at what constitutes reasonable policies, it makes sense to strive toward safe and secure systems for all modes of transportation. Few, if any, politicians or other decision makers would advocate for an unsafe or nonsecure system. Therefore, the more difficult question is to define what the term “safe and secure” means, and how we can plan for and build infrastructure that gives us safe and secure systems.

Safety and security policies may be set on local, regional, national, and international levels. An example of an international-level “safety” convention is the Rights of the Child, adopted in 1959 by the UN General Assembly, which defines children’s rights to protection. The act certainly does not have a focus on traffic safety, but one of the four core principles of the convention is the child’s right to life, survival, and development. Another of the core principles is “devotion to the best interests of the child,” and a third is “respect for the views of the child.” The convention is supported worldwide with barely any exceptions. The United States has signed the convention, but it has not been ratified by the US Congress, and the United States is thereby the only United Nations member state that is not a party to it. There are also conventions and standards that are international but not covering all or most of the world, such as European Union agreements.

As the title indicates, this article has a focus on transportation infrastructure. For a system to be safe and secure, it is obvious that one cannot see infrastructure in an isolated way. Motor-vehicle crashes, bicycle and pedestrian falls, and to a lesser extent rail, ferry, and airplane crashes, are typically caused by human error. But the likelihood of human error can certainly be influenced by infrastructure design. It is often stated that 90% of automobile crashes are caused by human error, but 90% of the crashes can be avoided through engineering measures. Though that latter part of the statement includes changes both to vehicles and to roadways, so infrastructure cannot do it all alone. The emphasis of this article is on personal safety and to some extent security. Long-term security with respect to preserving our current transportation infrastructure also could have a focus on climate change and global warming. With oceans rising, much of our road system as well as rail and airports may be flooded. These aspects are not covered in this article.

If a person wants to travel from A to B, their desire is typically to be able to do so as quickly as possible—or in a reasonable amount of time—with high comfort, at a low cost. They may also desire that it is an interesting experience, that it gives them exercise (if walking or riding a bicycle), and that they are not exposed to high levels of pollution. People typically assume that they will get to their destination safely, except that some people are fearful of walking or riding a bicycle through an “unsafe” neighborhood. Some people also have a fear of flying and think there is a high probability that their airplane will crash. Such fears can definitely be justified, especially if they fly by helicopter or a single-engine small propeller plane, but commercial jets are the safest mode of transport we have. Still, even commercial airplanes do crash, and when two Boeing 737 Max airplanes recently crashed—Lion Air in October 2018 and Ethiopian Air in March 2019—not only did people fear that the specific model of plane was not safe, but authorities around the world also acted and within days of the second crash grounded all planes of that type. As travelers, we demand that airplanes are “safe,” but we accept much higher risks when traveling by other modes, especially those where we are in control as operators.

We are exposed to multiple risks to our health when traveling. These include accidents or involuntary crashes, voluntary crashes with the intent to commit suicide, or homicide, caused by operators—for example, drivers or pilots—and crashes caused by terrorists. Other events during travel that can hurt us physically or psychologically include assaults of different seriousness—from verbal abuse to rape and murder—and the risk of catching a disease, for example, a virus that leads to an illness such as COVID-19. When this article is written, in the early fall of 2020, COVID-19 has gone from being widespread only in a small part of China to entering nearby countries and in March 2020 becoming a pandemic spread more-or-less everywhere on earth. It has moved from

continent to continent primarily by airplanes but also by cruise ships, and then locally by people traveling from town to town. For travelers themselves, walking or bicycling, as well as traveling in a private automobile, are considered safe with respect to catching the virus as long as the person is physically distanced by 2 m or more from others, whereas traveling in confined spaces in airplanes and other public modes of transportation is considered a risk factor for transmission. The fact that the virus is spread while traveling is not primarily an infrastructure-related issue and will therefore not be covered here in detail. However, terminal and station designs can have a great impact on such risks. In general, outdoor environments are considered safer than indoor rooms, especially if the latter do not have adequate ventilation. Air conditioners circulating but not filtering the air adequately may be the biggest “infrastructure” risk factor. The width of sidewalks and multiuse paths can certainly also influence a person’s ability to physically distance themselves from other people. So is the number of users of a system.

There are many other health issues relating to traffic. Exposure to air pollution can lead to cancer and many other illnesses. The World Health Organization (WHO) estimated in March 2014 “that in 2012 around 7 million people died—one in eight of total global deaths—as a result of air pollution exposure” (WHO, 2014). Traffic is just one of many sources of air pollution but a significant part. A 2013 EPA study attributed an estimated 29,000 premature deaths in the United States alone to ozone and PM_{2.5} emitted by road traffic (Fann et al., 2013). Moving roads away from where people live can reduce the death rate. However, going to electric vehicles would have a much greater effect, and building an electric distribution network is an infrastructure-related decision.

In addition, findings by the WHO show that chronic exposure to noise in cities can make people sick and can even kill people. Traffic noise alone may account for 3% of deaths from heart attacks and strokes in Europe. Given that 7 million people around the world die each year from heart disease, the global death toll from traffic noise could be around 210,000 (MetroUK, 2008). Installing noise barriers along highways and locating homes and airports apart are examples of infrastructure investments making a difference.

Modes and Infrastructure

This article covers infrastructure and not vehicle or operator characteristics. Safety and security aspects of infrastructure include:

- Walking: Design of multiuse paths, footpaths, sidewalks, and roadways
- Bicycling: Design of multiuse paths, bike paths, bike tracks, bike lanes, and mixed roadways
- Travel by private motor vehicle, including two-wheelers and trucks: Roadways and rest areas
- Travel by bus: Design of bus stops, bus terminals, and roadways
- Travel by train: Design of train stations and railways, including grade crossings
- Travel by airplane: Design of airports
- Travel by ferry and cruise ships: Design of ports and terminals

The short overview here cannot be exhaustive but will touch on some of these issues.

Risks When Traveling by Different Modes: Rail and Air

It is obvious that people accept some type of risk when they undertake certain activities, such as mountain climbing or downhill skiing. People traveling by car are also subject to a clear risk of getting injured, and since they typically undertake trips “voluntarily,” it can be argued that they implicitly accept the risks they are subjected to.

It also can be argued that people accept higher risks when they are in control of operating a vehicle than if they are the passenger of one. If we injure ourselves when driving a car, and it was primarily our own fault that the crash happened, we may not feel that we should blame the road administration even if what caused the injuries were collision with trees within the right-of-way area, and those trees could have been removed. On the other hand, if someone is killed when traveling by bus or airplane, many would blame the driver as well as the company operating the system, or the manufacturer of the vehicle/airplane, irrespective of if the driver/pilot were partially at fault or not. Why is that? Why should travelers not be equally safe when operating a mode themselves as when being passengers?

Let us look at the risk of getting killed when using some of our most common transportation systems. The risk of serious injuries should also be covered, but for brevity, only fatalities are discussed here partly because the definition of death is more uniform, and data quality is typically higher.

In EU-28, a total of 219 rail passengers were killed in the 5-year period, 2012 to 2016 (European Union Agency for Railway, 2018), giving an average death toll of 44 per year. That includes passengers killed in collisions and derailments as well as falling on board or when alighting or boarding trains and so on, excluding only confirmed suicides. Overall, with 44 fatalities per year, EU-28 saw around 0.086 fatalities per million inhabitants. For the average person, the annual risk of a fatality—the mortality rate—would be around 1 in 12 million. Is that safe? Another way of looking at it is that the average European in 2018 traveled 925 km/year by train (calculated as 472 billion km/510 million people), giving an average fatality rate to go by train in Europe of 0.09 fatalities per billion passenger-kilometer, or one fatality per 10.8 billion kilometers. Is that “safe”?

If we look at scheduled commercial air traffic in the United States, to get another estimate of actual fatality risk, and include all crashes and other accidents since January 2002, we have had 131 people killed on US airlines. Only one person was killed in a “large” US airliner between February 2009 and the writing of this article. Another three people were killed in the United States traveling by a

foreign airline (Asiana Airlines) when it crashed in 2013 for a total of 134 fatalities in the United States in the last 18+ years. So, from 2002 to the beginning of 2020, 18 years, we saw on average 7.4 fatalities/year, or around 0.025 fatalities per million inhabitants in the United States. And, if using 2018 US passenger travel mileage, 730.7 billion passenger-miles by plane, which is 1176 billion passenger-kilometer, as exposure, we get an estimate of passenger flight distance. Travel volumes have increased over the 18 years, and the average travel mileage may be around 1000 billion km/year. That means we saw around 0.007 fatalities per billion km, or 1 fatality/140 billion km. Is that safe? Well, it is about 13 times safer than being on a European train. And, if we look at the latest 10 years only, with four fatalities on commercial airplanes in the United States, we would be at around 0.0004 fatalities per billion person-kilometer. The risk of a fatality in the last 10 years would then be around one per 3000 billion km. Maybe we could agree that this is “safe”?

How many additional deaths related to European rail or US air traffic occur if we include “passengers” killed at terminals and stations? These fatalities could be caused by accidents or terrorist attacks or natural disasters such as hurricanes and earthquakes. The answer is that very few people have died in such events in recent years on these continents. However, if we include transport to and from airports and terminals, as motor-vehicle passengers or pedestrians, there are numerous fatalities every year.

Risks When Traveling by Automobile

Most travel do not involve US airlines or European trains, which were discussed earlier. If we look at automobile travel, do motor vehicles keep their occupants “safe”? One meaning of “safe” would be having a fatality rate below or similar to European trains, 0.09 fatalities per billion km? Or better, below the risk of flying in recent years in the United States, with 0.0004 fatalities per billion km. Let’s look at the US roadway system, using 2017 data. The United States that year had an official VMT of 3,212,670 million vehicle-miles according to the Federal Highway Administration (FHWA). With an average of 1.3 occupants per vehicle, that translates to 6,719,940 million people-kilometer. And, if we accept only 0.0004 fatalities per billion km of travel—to be as safe as air travel—we would accept only three automobile-related fatalities in the United States in 2017. Alternatively, if we accept our highway motorists to be no less safe than people in European trains, we would accept up to 0.09 fatalities per billion passenger-kilometer or 605 people killed. In reality, the United States saw over 37,000 fatalities in 2017 and 23,551 of those were occupants of motor vehicles according to the US National Highway Traffic Safety Administration (NHTSA). That is over 8000 times higher than what we could have as an objective required safety level, the safety level reached by commercial airlines in the United States or around 40 times higher than that of trains in Europe. Safety-wise, European roads do a bit better than US roads but are still far riskier than the potential desired levels as outlined earlier. The EU has seen right around 12,000 motor-vehicle occupant fatalities per year in later years (2013–16).

How can we make travel by automobile safer? In most countries, a great number of crashes are of rear-end type. These can be reduced by having low-speed variation between different users and along roads. Abrupt and drastic changes of speed is the worst, such as congestion on high-speed roads and change of speed from “high” to zero as is the case when a signal turns amber and then red. Signalization should therefore probably not be used where speeds are above 50 km/h. Well-built roundabouts give predictable speeds, since everybody slows down to 30 km/h or less even when there are no conflicting vehicles. In addition, high-speed highways should have variable speed limits, strictly enforced, that are reduced when traffic volumes are high. However, rear-end crashes cause few serious injuries and deaths. Rather, lane departure crashes make up a majority of fatalities. These can be divided into run-off-road and head-on collisions. Both these types can be mitigated with rumble strips, see for example [Gärder and Davies \(2006\)](#). However, rumble strips will far from eliminate these crashes. Cable barriers or concrete New-Jersey-style barriers are much more effective in eliminating head-on collisions and keeping vehicles away from unsafe roadside areas and should be used not only on multi-lane highways.

Risks for Unprotected Road Users

Unprotected road users have higher risks than automobile occupants. That is true for nonmotorist as well as for powered two-wheelers. If we look at motorcyclists, NHTSA reported that 5,172 motorcyclists and 23,708 passenger-vehicle occupants were killed in 2017 in the United States in spite of motorcycle crashes accounting for only 0.6% of vehicle kilometers traveled on America’s roads ([FHWA, 2019](#)). The risk per kilometer is much higher for motorcyclists than for automobile occupants. Still, passenger-car travel can be seen as the greater threat to public health since more people are killed in cars than on motorcycles.

If we look at the safety of nonmotorized, active modes of transportation, there is great variation between countries and between age groups as well as gender. Findings by [Buehler and Pucher \(2017\)](#) show fatality rates per kilometer traveled in Germany and the United States. We find that the fatality rate for senior (above age 65) pedestrians is roughly twice as high as for the population as a whole in both the United States (21.5 vs. 9.7 per 100 million kilometers walked) and Germany (3.8 vs. 1.9). Similarly, the fatality rate for senior cyclists is much higher than average in both the United States (7.6 vs. 4.7 per 100 million km cycled) and Germany (4.2 vs. 1.3). Children have lower fatality rates per kilometer walked than the population as a whole in both countries: 2.9 versus 9.7 (United States) and 0.9 versus 1.9 (Germany). Children also have slightly lower fatality rates per 100 million kilometers cycled: 4.1 versus 4.7 (United States) and 0.9 versus 1.3 (Germany). So, if we were to accept only 0.0004 fatalities per billion kilometers traveled—the approximate crash risk when flying in the United States—the risk for walking and bicycling is between 20,000 times too high (for children bicycling in Germany and 500,000 times too high (for older pedestrians walking in the United States). Obviously, the risk varies from location to location, and not all elderly people face the same risks, and risks may be even higher in other countries than

the United States. But most of us would and should agree that people often are not safe when riding a bicycle or walking. Since these modes are the most dangerous of main modes, it makes sense to focus more on these. And, if looking at mortality numbers, walking in particular is a safety issue, so the rest of this article will focus on pedestrian safety and infrastructure needs.

Pedestrian Safety

How can we make our transportation system safer for pedestrians? Obviously, pedestrian safety cannot always be maximized since the safety of bicyclists and motorists may at times conflict with the safety of pedestrians. Efficiency of traffic movements and environmental concerns also need attention. Moreover, construction and maintenance costs are important factors. Having said that, using designs, which are safe for pedestrians, typically also leads to high safety for other road users. Safety for everybody combined with efficient mobility, that is, short delays for motorists accomplished by the concept “quick but slow” often go hand in hand, such as when utilizing roundabouts along arterial streets rather than signalized intersections. One of the first studies to quantify the “quick but slow” concept was performed along South Golden Road in Golden, Colorado in the United States (Isebrands et al., 2008). This study showed a reduction in travel times by 10 s over an 800-m segment (quicker), while the 85-percentile speeds were reduced from 76 to 53 km/h. Safety was improved. Prior to construction of the roundabouts, there were 10 injury crashes per year, and in the four years after the roundabouts were built, only 1 injury crash was reported (Hartman as cited in Isebrands et al., 2008). Studies of pedestrian safety in Europe have shown that installation of single-lane roundabouts reduce pedestrian crashes by about 75% to 80% compared to signalization (Brude and Larsson, 2000; Schoon and van Minnen, 1994).

There are many health benefits connected to active transportation. Walking is probably the form of exercise that has the fewest negative side effects in the form of injuries—as long as injuries caused by collisions with motor vehicles do not happen. Empirical research by the US National Cancer Institute and Harvard University, following 661,000 adults during a 14-year period, found that just over an hour a day of moderate exercise, such as brisk walking, is optimal for longevity (Reynolds, 2015). But if pedestrians are exposed to excessive levels of air pollution from high volumes of traffic, these benefits decrease (Amorim et al., 2013).

There are obviously people with health problems who cannot walk, at least not far. However, if we include riding a wheelchair under the general umbrella of “walking,” most of us can and do walk, at least sometimes. So why do we not walk more? Probably because health benefits are not immediate. We do not want to sacrifice minutes today for a gain later in life. We feel that we do not have time to spend 30 min on walking when we can get there in 5 min by car.

It is important that children have safe and secure opportunities to walk to school. Walking may become a lifelong habit if it is started in childhood. Parents often worry more about a child being kidnapped or assaulted than about traffic, but as is pointed out by the British author Warwick Cairns, author of *How to Live Dangerously*, “. . . an average child would have to stand outside alone for 750,000 hours unsupervised to be kidnapped by a stranger. At that point, the child would be 85 years old” (USA Today, 2015). So, while we inflate some risks, we tend to neglect other risks, such as obesity and diabetes, which may occur if children are driven to their destinations.

People of all ages need to have “inviting” environments to be encouraged to walk, for example, to shops and restaurants. A building's entrance should be at the street with safe access directly from a sidewalk. Parking should be below, behind or on the side of buildings—not in front. It is also important for pedestrians to see others walking in an area. Mixed development—with restaurants, shops, offices, and apartments—means that there will be pedestrian activity during daytime as well as evening hours. Making the facilities attractive can by itself promote safety and security. The risk of assault, rape, or other violent crimes are reduced with pedestrian volume. And if drivers see many pedestrians near a street, they are more likely to slow down and yield to pedestrians. But safe infrastructure is still needed. Education and enforcement is seldom a substitute for safe physical layout but can be important complements.

Pedestrians should not only be allowed to walk “everywhere” but should be encouraged to do so. Providing sidewalks is a part of this. One type of roadways where pedestrians are not allowed is the motorway; however, other major roads should have sidewalks along them whenever there are substantial numbers of pedestrians, unless there are nearby parallel footpaths. The question becomes what constitutes a “substantial” number? Is one pedestrian an hour enough to motivate sidewalks? Can economic arguments allow us to keep operating an arterial-road-lacking sidewalk even if there are hundreds of pedestrians walking along it every day? If so, should the speed along it be restricted to 30 km/h even in rural areas? The current standards in Sweden are that rural roads need separate pedestrian and bicycle facilities when the combined pedestrian and bicycle volume is 100 per day (during summer months). If the pedestrian and bicycle flow is below 100 per day and annual average daily vehicle traffic (AADT) is above 2000, paved shoulders are acceptable. Mixed traffic is acceptable if AADT is below 2000 (Trafikverket, 2012). Finnish guidelines are similar but require separation of rural arterials already at 50 pedestrians or bicyclists a day if AADT is above 2000 (Gårder, 2018). Are those standards good enough? Maybe not if we are aiming for Vision Zero. We probably cannot get to zero risk but could we make walking as safe as flying by airplanes? As earlier pointed out, we would need to reduce risks by 99.99% for that to be the case.

A sidewalk is more attractive if it is set back from the roadway by a grass or vegetation strip (Gårder, 2018). Making the strip at least 2 m wide and having stem trees and/or utility poles separating vehicles from pedestrians will increase perceived safety, and a greater distance will reduce water and mud splashing from car tires. But a strip also increases actual safety if the sidewalk is removed from the clear zone. A *Policy on Geometric Design of Highways and Streets* (AASHTO, 2018), the so-called “Green Book,” defines a clear zone as the “unobstructed, traversable area provided beyond the edge of the travelled way for recovery of errant vehicles.” This guideline allows sidewalks to be within the clear zone, but it is clear that cars may traverse into it with some probability. For local roads and streets, the Green Book specifies, “a clear zone of 2 to 3 m or more from the edge of the travelled way, appropriately graded

with relatively flat slopes and rounded cross-sectional design, is desirable.” For higher-speed rural collector roads and arterials, the Green Book refers to the AASHTO *Roadside Design Guide* (AASHTO, 2011). That publication recommends that clear zones have a width of 9–10 m for flat, level terrain adjacent to a straight section of a 100 km/h highway with an average daily traffic of 6000 vehicles. The guide further states that for horizontal curves the clear zone should be increased by up to 50%. It would be prudent to not have sidewalks within this zone unless a barrier separates it from the road.

However, being on a sidewalk, no matter how close to a road, is not the most dangerous location for a pedestrian. Many crashes happen when pedestrians walk along roads lacking sidewalks and others when pedestrians cross roads. Several studies have shown that the lowest level of safety for pedestrians is found when they cross streets (Elvik et al., 2009). In order to reach a destination on foot, people need to cross streets and roads. The goal should be to provide “absolute” safety for pedestrians when crossing streets. Grade-separated crossings are not only expensive but may also not be used. If absolute safety cannot be provided, what is an acceptable safety level? That was discussed earlier, but Vision Zero goals—no fatalities and no serious injuries—should obviously remain the long-term goal.

In some jurisdictions, pedestrians have legal priority wherever they cross a roadway adjacent to an intersection. That is also the case in between intersections in some living-street environments (Woonerven, Home Zones, and so on) and in shared-space areas. However, in most locations, pedestrians have formal priority only in marked crosswalks and even there they may not be given priority. It can be noted that there are many gap acceptance studies where researchers have looked at pedestrians accepting and rejecting gaps between cars at marked crosswalks, but a few, if any, studies where someone looks at drivers accepting and rejecting gaps between pedestrians in crosswalks. Most of the time it is obviously up to pedestrians to find gaps even when they have the (formal) right-of-way. The absurdity of how pedestrians are treated needs to be highlighted. Pedestrians in marked crosswalks should not have to wait for a gap. Drivers crossing the crosswalk should look for gaps between pedestrians. Until pedestrians are given priority, crosswalks may cause more harm than good, since they often instill a false sense of safety, as highlighted more than 40 years ago by Herms (1972). Rather, we should provide crossing points at locations where the roadway is not wider than one (narrow) lane between raised refuge islands, at places where cars are traveling at “low” speed, probably never above 30 km/h. Encouraging pedestrians to cross where top speeds are above 50 km/h should never be done unless traffic volumes are extremely low and sight distances are good. If such conditions prevail, marking crosswalks is not needed. Marking crosswalks can lead to more crashes, especially on multilane streets (Zegeer, 2005; Zegeer et al., 2002). That does not mean that we as planners or engineers do not have an obligation to help pedestrians safely cross urban streets as well as rural roads. And that should apply to pedestrians with visual impairments as well as mental or physical handicaps. Geometric features that help pedestrian safety include more or less anything leading to lower speeds and shortened crossing distances (Gärder, 2004; 2018).

One reason speed is important for safety is that pedestrians accept shorter vehicle time gaps when speed increases. Pedestrians, especially the elderly, tend to go for constant distance gaps (Yannis et al., 2013). Lower walking speeds of the elderly and people with disabilities is also an issue. For drivers, higher speed is correlated to an increased likelihood and severity of a crash, but for pedestrians lower crossing speeds lead to greater risk (Shinar, 2008). Low vehicle speeds can be achieved simultaneously with narrow crossing distances if the roadway width is so narrow that it by itself slows down traffic. This is difficult to achieve if we want wide trucks and busses to be able to pass through. Very effective is a 2.1-m curb-to-curb distance, as has been done at some locations in the United Kingdom (see Fig. 1). If curb-to-curb width is much wider than that, for example, 2.8 m, many motorists will drive at speeds well over 30 km/h.

Figure 1 Example of a narrow travel lane slowing down drivers.

Another way to reduce speed is to make the geometry induce horizontal or vertical g-forces on the vehicle so that it becomes uncomfortable—or impossible—to drive fast. Small intersections or mid-block traffic circles can do this, and they can reduce median speeds to around 25 km/h and 85-percentile speeds to around 30 km/h. The Watt's hump as well as speed cushions can also achieve speeds in the 30 km/h range, whereas most speed tables with 8–10 cm height have 85-percentile speeds in the 45 to 50 km/h range (Johansson et al., 2003).

A relatively new invention is the “Actibump,” which is a “trap-door” bump activated only when a vehicle is going a set number of km/h above the posted speed limit. Actibump is a commercially developed product by the Swedish company Edema and that or similar devices can be used at crosswalks where low speeds need to be ensured. An alternative to this product is a system where drivers get a red light when they speed. Los Angeles, California, has experimented with such a system since 2014 on North Figueroa Street, at Amabel Street. There is a Your-Speed activated sign which triggers a downstream traffic signal to turn red if an approaching motorist exceeds the speed limit by more than 8 km/h (5 mph), forcing the motorist to come to a complete stop (S. Skehan, personal communication, March 18, 2015). A system like this can be combined with a red-light-running camera if motorists start ignoring the signal. An advantage with a system like this compared to direct camera enforcement of speeds is that it is politically easier to implement.

A Swedish study from the 1980s found that scramble—that is, pedestrians having a simultaneous walk phase on all crosswalks while all cars are stopped—is ineffective in promoting pedestrian safety unless red-walking frequencies are very low, and that red-walking frequencies become high when wait times are long, which is the case when scramble is used (Gårder, 1989). The study also found that left-turning vehicles are involved in many pedestrian crashes so that there is no easy way of using signalization as a way to improve pedestrian safety (Gårder, 1989). Other studies confirm that left-turning vehicles pose more of a threat to pedestrians than right-turning ones (in countries where people drive on the right). Reasons include higher speeds and opposing traffic-blocking view of the crosswalk (Lord, 1996; Lord et al., 1998).

Analysis of crashes in general shows that few multivehicle crashes happen without any of the parties taking evasive maneuvers prior to the impact. A study by Walz et al. (1983) found that only 18% of the fatal crashes had collision speeds equal to the traveling speed of the striking vehicle. In 62% the collision speed was reduced by at least 20% before striking a pedestrian. And lower speeds lead to higher probability of having started braking. They also reported that a reduction of the speed limit from 60 to 50 km/h was accompanied by a 25% reduction in pedestrian fatalities. However, the classic study on speed safety relationships is by Teichgräber (1983) who reported a probability of death for a pedestrian hit by a car as 10% at 20 km/h, 20% at 30 km/h, 30% at 40 km/h, 60% at 50 km/h, and 95% at 70 km/h. A Swedish study, based on the largest in-depth pedestrian accident study ever undertaken (at least at that time), shows that for adult pedestrians hit by the front of passenger cars, the fatality risk at 50 km/h is more than twice as high as the risk at 40 km/h and more than five times higher than the risk at 30 km/h (Rosén and Sander, 2009). And studies of real traffic show that pedestrians face 50 times higher risk when crossing a four-lane street posted at 55 km/h than when crossing a low-speed, two-lane street where drivers are traveling at speeds around 30 km/h (Gårder, 2004).

In conclusion, pedestrians are usually not killed or even seriously injured when hit by a car moving at a speed of 30 km/h or less at impact. Ensuring low speeds and short crossing distances should make most pedestrians safe. However, pedestrians who are intoxicated, or distracted, may walk out in front of a moving car and be seriously injured at moderate speeds. As previously pointed out, it should not be up to pedestrians to look for gaps between cars, but drivers should look for gaps between pedestrians. ITS functions can be structured to aid pedestrians with this (Leden et al., 2014). Auto-brake and eventually autonomous vehicles will lead to higher safety, but we need to design our infrastructure to be safe before that happens.

Conclusions and Discussion

People should be encouraged to use the safest available modes. That is typically trains and airplanes. Providing infrastructure for these modes should be a policy priority around the world. Automobile traffic is today far from safe in all countries, and we need to improve this, partially by redesigning our infrastructure. However, we also need to encourage walking as a mode of transportation since walking promotes better health and produces no air pollution. It must be “safe” to walk. Arterial and collector roads must have sidewalks. The sidewalks should be separated from the roadway by a curb and/or wide separation strip in higher-speed areas. Safe crossing points need to be provided. Pedestrians' interests rather than automobile traffic should be the policy priority.

The numbers referred to in the introductory sections relate to unintentional crashes, so-called accidents. If we add intentional crashes, suicides and homicides, the numbers do not change drastically. The same is the case if we add terrorism and piracy. Carjackings are fairly common in some countries, including South Africa and the United States, but a few of them lead to murder or death in any other way. Of course, death is not the only outcome that should be analyzed, and worldwide there are annually thousands of carjackings leading to traumatic experiences. Road piracy where people are robbed is also a safety issue. Piracy on our oceans where ships are captured sometimes leads to people being kidnapped and held for years, and in some years scores of people are killed.

If we look at transportation related illnesses that injure or kill travelers, we should look at excess injuries and deaths, rather than total injuries and deaths that occur while people are traveling. People spend, on average, about an hour a day traveling, mostly by motor vehicles. Obviously, people can have medical issues such as heart attacks and strokes during these times. However, the incidence rates of some illnesses may be higher when traveling than at other times. For example, sitting still in airplanes for long periods may lead to higher incidents of blood clots than “normal” activities. Road rage, or stress, while driving or bicycling can lead

to increased blood pressure and pulse rates, which in turn lead to stroke and other illnesses. However, infrastructure design should seldom be blamed for this.

Biography

Per Erik Gårder is a professor of Civil Engineering at the University of Maine, US, since 1992. He has a PhD from Lund University in Sweden, and he was, from 1983 to 1992, a faculty member of the Royal Institute of Technology (KTH) in Stockholm, Sweden. His research interest focuses on forecasting, designing, and evaluating facilities with emphasis on traffic safety.

Introduction

Sensors are an essential part of any Intelligent Transportation System (ITS), which can play a vital role in collecting real-time information for transportation systems. The applications of advanced sensor technologies to surveillance, control, and management of transit networks have become increasingly widespread in practical terms. Infrastructure-based sensor technologies, counting sensors, image sensors, inductive loop, microwave radar, video camera, and more recently Bluetooth, Wi-Fi signal and smartphone-based sensors are the most commonly-used technologies for long- and short-term traffic detection (Antoniou et al., 2011; Zhao et al., 2019). Both traffic operation agencies and highway users can reap the benefits of having access to comprehensive and precise knowledge of the real-time traffic information. For example, from the viewpoint of traffic management agencies, designing network-level travel time surveillance can bring real-time information on both temporal and spatial traffic state patterns, leading to a more precise travel behavior analysis. In addition, one of the simplest ways for traffic operation agencies to detect bottleneck locations and the spatiotemporal propagations of the traffic queues is to use raw traffic data (e.g., vehicle count, time–mean speed, or occupancy) collected from fixed traffic sensors. Accordingly, in the past few years, a large amount of literature has been devoted to the problem of optimally locating sensors on a traffic network in order to measure traffic flows accurately (e.g., Bianco et al., 2001; Hu and Liou, 2014).

In general, traffic sensor technologies can be categorized into three different groups, including intrusive, nonintrusive, and off-roadway technologies (Bottero et al., 2013). Intrusive sensors are fixed in or on the pavement, whereas nonintrusive traffic sensors can be installed overhead or on the side of the pavement with minimum disruption to normal traffic operations. Off-roadway technologies refer to those that do not need any specific equipment to be mounted under the pavement or on the roadside, for example, this group involves probe vehicle technologies with GPS – WAAS (EGNOS, in Europe) and mobile phones, which can be also combined with automatic vehicle identification (AVI) systems, and remote sensing technologies using images from satellite. The data collected using sensor systems can then be used to monitor traffic congestion levels and incidents on freeways, predict travel times, estimate OD flows, and support decision making for transport agencies (Sun et al., 2016).

With the rapid development of new technology, there are several tools to obtain detailed information through on-vehicle equipment, such as Wi-Fi and Bluetooth-equipped devices, which can provide high-resolution data for the entire trip of vehicles equipped with such sensors. Indeed, the sensors can capture the public parts of the Bluetooth or Wi-Fi signals within their coverage radius, which can make it possible to use several different matching algorithms to detect and track a device, when it is connected to a sensor. For example, if a vehicle, which has been equipped with a Bluetooth device, travels along a freeway corridor, it can be logged and time stamped at time t_1 by a sensor at location 1. After crossing a certain distance, it can be again detected and time stamped at time t_2 by means of a sensor at downstream location 2. Wi-Fi signal sensors can also discover the signals produced from Wi-Fi modules installed into different mobile devices. The Wi-Fi modules are defined based on IEEE 802.11 standard (IEEE 802 Group, 2010). The basic unit for data exchanged between devices is known as frame. Several different types of frames are defined in the standard protocol, namely Beacon, Acknowledgment (ACK), Data, and Probe. Each access point periodically sends Beacon frames to show its availability. If a mobile device is connected to an access point, information is transferred using Data or ACK frames; otherwise it sends Probe frames to look for existing access points. The information that can be detected using Wi-Fi signal sensors are: Media Access Control (MAC) addresses of the mobile device and the access point, frame type, time stamp, and signal strength correlated directly with the distance between Wi-Fi sensor and mobile device. Accordingly, by detecting the MAC address at multiple locations over time, a person will be tracked unless he/she turns off Wi-Fi or switches to airplane mode (Ji et al., 2017).

In summary, embedding sensors into a complex transport network can considerably increase the socio-economic benefits by providing sufficiently detailed traffic state information to users and operators. Moreover, a broad range of data mining and prediction methods can be employed for analyzing raw traffic data collected using sensor technologies.

The present article provides a review on the applications of traffic sensors, ranging from traditional ones to mobile sensors in smartphones, to surveillance of transportation networks, including travel time estimation (Travel Time Estimation Section), origin–destination matrices estimation (Origin–Destination Matrices Estimation Section), safety analysis (Safety Analysis Section), driver behavior monitoring (Driver Behavior Monitoring Section), and transportation mode inference (Transportation Mode Inference Section).

Travel Time Estimation

One of the main factors in the evaluation of a transport network is the congestion level measured in terms of delays and travel times. Real-time analysis of travel time is of great importance for traffic management and for providing information to commuters. Hence, the problem of locating traffic sensors on a transit network for travel time estimation is becoming a common trend in transportation research. Travel time estimation is practically performed from data collected on vehicle flows, speeds, queues, densities, and so on. The required data can be collected either manually (questionnaires, surveys, census, or even standing at street corners and counting vehicles), or through installing sensors (hardware and software) (Gentili and Mirchandani, 2018). The manual methods can lead to issues such as high respondent burden, small sampling rates, high data collection costs, short survey duration, and low data quality.

Chen et al. (2004) investigated the AVI reader location problem for both travel time and OD prediction applications. Three different location section criteria were taken into account when deciding locations for AVI readers: the minimization of the number of AVI readers, the maximization of the coverage of OD pairs, and the maximization of the number of AVI readings. To satisfy all three objectives, the problem was formulated as a multiobjective integer-optimization problem. Sherali et al. (2006) also developed a discrete optimization model for optimally locating AVI readers to estimate roadway travel times. A solution method based on the Reformulation–Linearization Technique combined with semi-definite programming concepts was proposed to solve the problem. Ban et al. (2009) proposed an optimization framework and a polynomial solution method for finding the optimal locations of point detectors employed to estimate freeway travel times. The objective of the model was to minimize the deviation of the actual and estimated travel times on link segments along a freeway route. Antoniou et al. (2013) developed a methodology for the identification and short-term prediction of traffic state, taking advantage of the ever-increasing accessibility of traffic data collected from emerging sensor technologies. For reliable travel time estimation, Park and Haghani (2015) developed a deterministic, a stochastic, and a dynamic formulation to find the optimal location of Bluetooth sensors, taking reorganization of sensors in a freeway corridor into account as well. Indeed, this method allows for the inclusion of traffic uncertainties into the problem, thus investigating scenarios which are more likely to occur.

In the vast majority of the previous studies, the active traffic sensors are totally installed at nodes of a traffic network and not at links; hence, the adjacent links of those nodes should be equipped with sensors, leading to a high cost. Zhu et al. (2018) developed a novel data-driven link-based network sensor location approach with the aim of maximizing travel time information gain. The underlying assumption is that the active sensors can be installed at links rather than at nodes. Moreover, the influence of route differentiation, as well as the uncertainty of travel time data are taken into account to robustly locate active sensors.

Mobile sensors in smartphones enable collection of high-resolution vehicle performance data in a cost-effective way. In recent years, there have been a growing number of publications focusing on the use of cellular phones with GPS data as the most common source of real time information to estimate travel times. For example, in the work of Amirian et al. (2016), the authors used several machine learning methods to improve the estimation of travel time for pedestrian mode. The dataset contains several different features, such as age, length of journey, change of elevation, day of week, time of day, weather condition, and gender. For instance, the length of journey for current day attribute was recorded using digital pedometer sensors on smartphones. The results showed that a random forest method can lead to a better performance compared to other methods tested, including gradient boosting, least squares, least-angle regression (LARS), least absolute shrinkage and selection operator (LASSO), K nearest neighbors, and Adaboost methods.

Origin–Destination Matrices Estimation

So far, a large number of studies have been carried out on the estimation and prediction of OD flow using data collected by traffic sensors in a cost-effective manner rather than the estimation of network origin–destination matrices based on traffic flow observations (Hadavi and Shafahi, 2016). The quality of OD demand estimation can be directly affected by the amount and quality of traffic data collected using different types of traffic sensors. Hence, finding the optimal number and installation locations of traffic surveillance sensors in view of the existing budget constraints of transit agencies, which is known as the network sensor location problem (NSLP), is of great importance for the estimation of a set of unknown network OD matrices at a high level of accuracy (Bianco et al., 2001).

The NSLP can be classified into two sub problems (Gentili and Mirchandani, 2012): the sensor location flow-observability problem (e.g., traffic flow inference), and the sensor location flow-estimation problem (e.g., OD estimation problem, travel time estimation). Three methods have been employed to solve the NSLP in the literature (Hu and Liou, 2014):

1. The mathematical optimization method with the aim of maximizing flow covers or minimizing specific requirements under a set of constraints, for example, budget constraints.
2. The algebraic method, in which one-step or iterative actions including matrix algebra based on specific incidence matrices, for example, the link–path incidence or the link–node incidence matrices are used to find a set of deployed links.

3. Graph theory, in which the spatial correlations between nodes and links within a network structure are disintegrated to find a set of critical links.

The space-state formulations based on Kalman Filtering are known as an efficient method for the estimation of time-dependent OD flows (Antoniou et al., 2007). Accordingly, Barceló Bugeda et al. (2012) developed a novel recursive linear Kalman-Filter approach for the estimation of time-dependent OD matrices from the measurements of traffic variables, taking the advantages of travel times and traffic counts collected by tracking Bluetooth equipped vehicles and traditional detection technologies. Hu et al. (2001) also developed a Kalman Filtering approach for the estimation of dynamic OD matrices, in which time-varying parameters as state variables were incorporated into the model formulation. Indeed, the Kalman-Filter method presented is able to cope with the nonlinear relationship existing between the state variables and the observations.

Antoniou et al. (2004) developed a methodology for the incorporation of automated vehicle identification (AVI) data into O-D estimation. Indeed, O-D estimation and prediction was carried out for both cases: the base case (no AVI information) and in the presence of AVI information. The results showed that the inclusion of additional data sources (e.g., information obtained from AVI systems) can improve the accuracy of the O-D estimation. Zhou and Mahmassani (2006) developed a novel OD-demand-estimation method in order to extract OD-demand distribution information from AVI counts without the inclusion of market-penetration rates and identification rates of AVI tags in the demand-estimation problem. A nonlinear ordinary least-squares estimation model was developed to amalgamate AVI counts with other available data sources into a multi-objective optimization framework. Ji et al. (2017) proposed a hierarchical Bayesian model to predict trip-level OD flow matrices and a period-level OD flow matrix using sampled OD flow data collected by the combination of farebox and Wi-Fi signal sensors data on a public transportation system. The model is also evaluated empirically on a real bus corridor, demonstrating the possibility of merging farebox and Wi-Fi signal sensors data to improve data quality and enlarge dataset that enable transit operators to attain sufficiently detailed transit route-level passenger travel patterns, and to derive latent aspects of passengers' travel behavior as well.

While a considerable amount of literature has been published on the NSLP, there is a notable paucity of well-controlled studies that seek to identify an optimal sensor configuration minimizing performance monitoring errors while taking the probability of sensor failures into account. To fill this gap, Danczyk et al. (2016) developed a probabilistic optimization model for the sensor allocation problem along freeway corridors, which minimizes the traffic measurement errors while taking all the plausible failure scenarios into consideration.

Safety Analysis

Traffic network surveillance using sensor technologies is also of great importance in real-time safety analysis, which can be applied to enhance incident detection capabilities and improve traffic control systems by exploring the relationship between real-time traffic features and crash occurrence (Yuan et al., 2018).

Petraki et al. (2020) used high-resolution driving behavior data collected from sensors of smartphones of 303 different drivers to investigate driver behavior at both road segment and junction levels. The dataset was also accompanied by traffic features (traffic flow and speed) collected via 26 loops installed over specific measuring positions on the two urban expressways under study. For the data analysis, two log-linear regression models were calibrated for road segments, as well as two linear regression models were developed for junctions. The results demonstrated that the number of harsh events can raise in road segments as the mean traffic flow per lane increases in the respective areas. Moreover, the increase of the average occupancy in junctions can lead to a rise in harsh accelerations, as well as when the average speed raises, more harsh deceleration events happen. The driving patterns along a route can be extracted from microscopic traffic measures (speed and acceleration profiles) obtained through the mobile sensor data. In the work of Paleti et al. (2017), mobile sensor data from smartphones was employed to derive latent driving patterns and to explore their relationship with traffic crash incidences. The findings showed that the microscopic traffic measures can significantly improve the data fit of crash frequency models.

The advent of several novel sources of information with an unprecedented volume, termed "big data", and state-of-the-art machine learning methods can support transportation researchers in finding appropriate solutions for the highway traffic safety system. Huang et al. (2020) have attempted to investigate the possibility of utilizing deep learning methods, which can automatically extract high-level features from input data, to detect crash occurrence and predict crash risk. The authors developed a deep learning algorithm on traffic data (volume, speed, and sensor occupancy) collected from roadside radar sensors for crash detection and risk estimation. The results indicated that a deep learning architecture can lead to a better crash detection performance and similar crash prediction performance compared to shallow models. Formosa et al. (2020) also proposed a deep learning methodology to leverage large imbalanced data for predicting real-time traffic conflicts. A large amount of disaggregated traffic data and on-board sensors data from an instrumented vehicle were collected over a section of the UK M1 motorway to construct the model. The authors took several different influencing factors into account in detecting traffic conflicts, such as speed variance, traffic density, speed, and weather conditions.

Driver Behavior Monitoring

With the rapid development of information and communication technologies (ICT), several different emerging data sources, such as GPS data, smartcard records data, roadside sensor data, and smartphone sensor-based data, have appeared and been applied to

supplement or substitute for traditional survey data to extend human travel behavior research. Of these, however, smartphone sensor-based data are the most widely applied and promising type, due to their growing penetration in the population, and their built-in location and motion sensors (Wesolowski et al., 2014). For example, smartphone-based vehicle positioning capability has resulted in collecting a massive data volume on the real-time location and dynamics of users, thereby providing a tremendous opportunity to monitor the operation of transit networks. Smartphone-based vehicle positioning methods have emerged since 2008 with the advent of GPS antennas and navigation maps in smartphones (Kanarachos et al., 2018).

In addition to GPS sensor, most of the modern smartphones are equipped with multiple motion sensors, such as accelerometer and magnetometer sensors, which can provide an unprecedented opportunity for the monitoring of the motion status of mobile phone users, thus improving the performance of transportation network surveillance. Indeed, these motion sensors enable transportation researchers to broaden their investigations in the area of travel behavior research by providing them with a considerable data volume collected on the real-time location and dynamics of users (Wang et al., 2018). The accelerometer sensors are used for estimating the acceleration and motion status of users in different directions, such as going up or down, standing, walking, cycling, and driving (Lane et al., 2010). The magnetometer sensors are used for detecting the orientation of a mobile phone device relative to the Earth's magnetic north. Overall, the recording of driving behavior in different conditions, either from smartphone sensors or from on-board device sensors has contributed to the collection of high-resolution data and objective measurements.

GPS positioning accuracy can be affected by a wide variety of factors, including the number of visible satellites, weather, and surrounding conditions such as buildings and trees (urban canyon effects) (Groves, 2011). Christopoulos et al. (2018) showed that the accuracy of the smartphone GPS position signal is on average 3 m, nevertheless, it can reduce significantly while crossing bridges and arriving at the urban area. Much of the available literature on smartphone-based vehicle positioning has focused on maintaining positioning accuracy when the GPS signal is weak (Chen et al., 2015). For instance, a possible way of enhancing the level of GPS position accuracy is to share the GPS information between smartphone of road travelers and other infrastructure objects of recognized GPS location. Nonetheless, the above-mentioned idea has been merely investigated in a simulation framework or using Dedicated Short-Range Communications (DSRC) vehicle-to-vehicle (V2V) communications (Bento et al., 2017).

The growing penetration of advanced smartphones equipped with a wide variety of built-in sensors (e.g., GPS, accelerometer, and gyroscope) and network interfaces allow for a more efficient development of connected applications used to monitor and recognize driving behavior in real time. Johnson and Trivedi (2011) developed a state-of-the-art system in which a Dynamic Time Warping (DTW) algorithm and smartphone based sensor-fusion (accelerometer, magnetometer, gyroscope, GPS, video) are used to detect driving events and driving style. The authors assessed the performance of multiple sensor fusion sets to detect lateral and longitudinal movements. Wahlström et al. (2015) developed a novel framework for detecting dangerous vehicle cornering events based on an updated test statistic estimated by an unscented Kalman filter applied to the global navigation satellite system (GNSS) measurements. They also evaluated the possibility of using inertial measurement unit (IMU) measurements in order to enhance the detection accuracy. Li et al. (2016) proposed a Safe Drive system which can determine the driving conditions with leveraging the built-in smartphone sensors. The authors proposed a precise driving condition classification algorithm-based on data collected from GPS and accelerometer sensors on smartphones. The findings showed that the algorithm can reach 87% classification accuracy in complex circumstances.

Castignani et al. (2017) developed an adaptive driving maneuver detection approach based on a Multivariate Normal distribution (MVN) model to detect risky driving maneuvers using smartphone sensors and GPS data. The results showed that the model can adapt to various road circumstances and vehicles. Saiprasert et al. (2017) proposed three various algorithms to detect and classify driving events using data collected from motion sensors of smartphones. The algorithms can also classify whether these driving events are aggressive. The experimental results indicated that a pattern-matching algorithm can outperform a rule-based algorithm for driving event detection in lateral and longitudinal axes. Recently, Johnson and Rajamani (2020) proposed a state-of-the-art algorithm to determine the position of a smartphone on a moving vehicle using the accelerometer, gyroscope and GPS sensors available on a phone. This detection can be used to recognize whether the smartphone is being used by a driver or a passenger on the vehicle. Hence, it can be useful for automatically restricting texting features when the phone is on the driver's seat.

Transportation Mode Inference

As discussed earlier, smartphones and their sensors are spreading more rapidly than expected as devices that can be used for monitoring driver behavior with leveraging their GPS trajectories data. In recent years, smartphone-based transportation mode inference has attracted considerable attention, both scholarly and popular. Kanarachos et al. (2018) carried out an extensive review of various sensor fusion approaches that are used for smartphone-based travel modes classification (see Table 1). The comparison has been carried out based on a Cybernetics paradigm, in which the signals, decision-making technique, sensor fusion level, and performance are taken into account.

Up to now, a large number of machine learning methods have been tested for the travel modes classification. As a comprehensive investigation, Xiao et al. (2015) demonstrated that Bayesian Networks can outperform Support Vector Machine (SVM), as well as SVM-based approaches are superior to Neural Networks. For example, they showed that Bayesian Networks can, respectively, lead to an improvement of 2.5% and 7% on the training and test sets compared to SVMs.

Table 1 Comparison of various sensor fusion approaches for smartphone-based classification of transportation mode

Reference	Signals			Method	Fusion	Accuracy
	Acceleration	Speed	GPS position			
Byon et al. (2009)	✓		✓	Neural Networks	Smartphone based fusion	60%–98%
Biljecki et al. (2013)		✓		Fuzzy expert	Smartphone based fusion	92%
Byon and Liang (2014)	✓		✓	Neural Networks	Smartphone based fusion	74%–83%

Summary

Sensors, which are a key part of any ITS, play a crucial role in collecting real-time travel data used to monitor traffic congestion levels, incidents on freeways, predict travel times, estimate OD flows, and support decision making for transport agencies. So far, a broad spectrum of sensor technologies has been evolved and used in the area of transportation systems, ranging from infrastructure-based sensor technologies to built-in smartphone sensors. The present chapter provided a wide-ranging review on the applications of various sensor technologies in travel time estimation (Travel Time Estimation Section), origin-destination matrices estimation (Origin-destination Matrices Estimation Section), safety analysis (Safety Analysis Section), driver behavior monitoring (Driver Behavior Monitoring Section), and transportation mode inference (Transportation Mode Inference Section). Thus far, researchers have mostly developed travel demand models based on raw traffic data collected through traditional sensor capabilities, which are expensive and can lead to issues such as short survey duration, and small sampling rates. On the other hand, emerging sensor technologies, such as smartphone-based sensors, can support transportation researchers to leverage state-of-the-art machine learning methods with a tremendous amount of mobility data for discovering daily travel behavior. Hence, this article has particularly focused on the review of the previous studies in which modern sensor technologies, such as Bluetooth, Wi-Fi signal, and smartphone-based sensors, are used for the monitoring of the dynamics of users.

Children's and Youth's Active Travel as a Planning Concern

Active and independent travel among children and youth became an area of planning inquiry in the 1970s. That era saw a shift from “outdoor” and “walking” children to “indoor” and “chauffeured” children. In response, two seminal works were published in the UK: Ward’s “The Child in the City” (1978) and Hillman’s et al. “One False Move” (1990). These authors advocated for transport safety and security measures on behalf of children and youth. Their concerns stemmed from the post-war suburbanization movement, which led to increasing distances and intense car use in middle-class peripheries. Meanwhile, urban cores became depleted of people and resources and consequently, safety and security therein declined. Attitudes changed too: the outside world came to be seen as a hostile, dangerous place where children were likely to be harmed by cars or adults. In combination, these trends limited both urban and suburban children’s free mobility and access to the city.

In the last decades, with growing concerns over obesity, climate, and liveability, studies on the travel of children and youth travel have multiplied, especially in Western Europe and North America (see Hillman, 1999; Mackett, 2013; McDonald, 2005; O’Brien et al., 2000). These studies have revealed that, compared to previous generations, the travel patterns of children here have changed enormously. The key findings from studies set in Western Europe, the Anglosphere, and elsewhere are unpacked below.

Active School Travel in Western Europe and the Anglosphere

Many western-based studies, most of them cross-sectional, have focused on the school commute of children and youth. Studies are so numerous that, by now several systematic reviews are available (Aranda-Balboa et al., 2020; Costa et al., 2020; D’Haese et al., 2015; Davison et al., 2008; Faulkner et al., 2009; Ikeda et al., 2018a, 2018b; Larouche et al., 2014b; Lubans et al., 2011; Pont et al., 2009; Rothman et al., 2018; Sirard and Slater, 2008; Wong et al., 2011).

The reviews show that parents have adapted to modern urban living by confining children to the home or by escorting and/or chauffeuring them in cars. Car travel has become a form of mobile childcare, while allowing children out unchaperoned is now regarded as a marker of neglectful parenting. Children themselves often mirror their parents’ habits and views in regard to travel (Zwerts et al., 2010). There is a strong positive association between active school travel and other physical activities (and cardiovascular fitness) but findings are less unanimous on the assumed link between active school travel and lower body mass index (BMI) (Faulkner et al., 2009; Sirard and Slater, 2008).

Based on these reviews, the rates of active travel to school are in the following ranges: 20%–78% in continental Europe; 47%–68% in the UK; 5%–49% in the US; 19%–33% in Australia, and 15%–61% in New Zealand. Some reviews separate statistics for walking and cycling, whereas others lump them together under the banner of “active travel.” Where the data are reported separately, staggering differences in walking and cycling rates are revealed. For example, in the UK a solid 40%–69% of school-children walk to school whereas cycling rates are abysmal by comparison, ranging between 0.2% and 9%. In the US, between 4% and 63% of children walk to school depending on the setting but only 0.8%–14% cycle.

The main factors consistently found to associate with active school travel in Western European settings and the Anglosphere are (not necessarily in order of importance): short home-school distances; lower socio-economic background; urban character of residential neighborhood; densely populated school neighborhood; land-use mix along route; conducive caretakers’ schedules; supportive parental attitudes; lower parental safety and/or security concerns; small school size; male gender of child; availability of pedestrian infrastructure and absence of busy road crossings or freeways en route; fewer or no cars in the household; and school zoning policies (e.g., forcing children to attend a school within their catchment area). Less common correlates include: older age of child; minority ethnic background; social support; peer influence; positive relationships with neighbors; street design (intersection density, pedestrian route directness, length and density of street segments, street aesthetics, street topography); lower parental education level; parental employment and marital status; and children’s positive attitudes toward active school travel.

The foregoing findings are subject to the caveat that, comparing studies on the school commute is rather difficult due to the heterogeneity of sample sizes, family composition, school systems, spatial units, cultural traits, and environmental features, all of which have been examined as potential predictors of active school travel (Mitra and Buliung, 2012). Even the definition of “child” and “youth” varies among studies—in terms of age range, with 5 or 6 being the lower limit and 18 being the upper limit. Some studies separate the “to” and “from” school trips because in western settings the return trip is complicated by afterschool activities and caregiver schedules (given that many children are chauffeured)

School Travel in Other Settings

Studies in settings other than Western Europe and the Anglosphere are much less extensive. Case studies are only available for: Albania (Pojani and Boussauw, 2014); Brazil (Becker et al., 2017; Costa et al., 2012; Dias et al., 2019; Melo et al., 2013); mainland China (Yang et al., 2017, 2019; Zhang et al., 2017); Colombia (Arango et al., 2011); Cyprus (Loucaides et al., 2010); India (Singh and Vasudevan, 2018); Iran (Mehdizadeh et al., 2017; Samimi and Ermagun, 2013; Shokoohi et al., 2012a, 2012b); Japan (Mori et al., 2012; Waygood and Taniguchi, 2020); Ghana (Siiba, 2020); Hong Kong (Barnett et al., 2019; Leung and Loo, 2020; Yang et al., 2020); Mexico (Jáuregui et al., 2015, 2016); the Philippines (Tudor-Locke et al., 2003), Taiwan (Lin and Chang, 2010), and Vietnam (Trang et al., 2012). Two systematic reviews are available, one for Africa (Larouche et al., 2014a) and one for Brazil (Ferrari et al., 2018). Hence generalizations are clearly difficult.

Based on these studies and reviews, the rates of active travel to school range from 20%–98% in Asia to 19%–79% in South-eastern Europe to 41%–71% in Latin America to 20%–100% in Africa. Again, few reports provide separate statistics for walking and cycling. Where separate figures are provided, cycling rates are shown to be much lower than walking rates. For example, a study based in China reports a 57% walking rate and a 12% cycling rate. Similarly, a study conducted in Albania reports a 67% walking rate and a 1% cycling rate.

With regard to determinants, the most consistent findings are not too different from those unveiled by the western-based studies discussed above, and include: short home–school distances; lower socio-economic background; protective attitude toward girls; urban character of school neighborhood; supportive built environment features (e.g., availability of sidewalks and parks); street connectivity and safety; parental safety perceptions; children’s age; parental travel patterns (level of auto-dependency); fewer or no cars in the household; less maternal education; and nonworking mothers.

Less commonly mentioned factors include: high tree-shade density along sidewalks; male gender of child; maternal driving licence status; parental physical activity habits; children’s attitude toward active travel; peer support; street aesthetics and topography; street size; higher population density along school route; mixed land-use pattern along school route; milder weather conditions; higher number of adults in the household; and availability/accessibility of public transport stops along school routes. Some factors emerge only in particular contexts. For example, in studies based in Africa, factors such as fear of rape, drawing, or attacks by wild animals deterred children, especially girls, from engaging in active travel to school.

The Road Ahead: Planning for Active School Transport

Children face many barriers to active school travel, particularly in wealthier and more car-oriented settings. Parental concerns around active school travel are mostly justified: road injuries are a reality and the quality of public outdoor spaces, especially in the poorer sections of big cities, has declined. Air, noise, and visual pollution caused by moving and parked cars, as well as poor urban design, with spaces unfriendly to walking, are widespread outside (historic) city centers. These concerns notwithstanding, automobility starting at an early age poses major risks from an environmental and public health perspective, as children’s current travel behavior may affect their future travel behavior as adults. Also, reduced physical activity and lack of exposure to the outdoor environment may affect children’s physical and mental health.

Hence, active school transport should be considered as a priority concern in public policy. Socio-economic and demographic variables that correlate with active travel (lower socio-economic background of child; male gender of child; older age of child; conducive caretakers’ schedules; and fewer or no cars in the household) may be difficult to modify. However, environmental and psychological variables (short home–school distances; urban character of residential and school neighborhood; supportive built environment features such as availability of sidewalks, parks, direct routes); lower parental safety and/or security concerns; and supportive parental attitudes and less auto-dependency in the family) can and should be tackled to enable and encourage more children and youth to walk and cycle to school. Following is a list of the most popular programs in this regard, which have been adopted around the world. Most have been reviewed by Duggan et al. (2018).

Walking School Bus. In a Walking School Bus, participating parents or other adults take turns acting as “drivers”: they set a walking route along which they pick up children and deliver them safely to school (Collins and Kearns, 2010; Kingham and Ussher 2005, 2007; Pérez-Martín et al., 2018). The program is thought to have originated in Australia in 1992 but there is evidence to suggest that similar practices had been in place in Japan since at least the early 1960s. In the new millennium, the Walking School Bus has expanded to Canada, Denmark, New Zealand, the United Kingdom, and the United States. Despite its benefits, this program tends to suffer from a shortage of adult volunteers sharing the workload. Therefore, it is concentrated in wealthier neighborhoods (Collins and Kearns, 2010; Kingham and Ussher, 2005, 2007).

Safe Routes to School. This program was first initiated in the United States in 2005 with the aim of boosting traffic safety along the school routes and in school environs (Duggan et al., 2018; McDonald and Aalborg, 2009). Strategies have included footpath improvements, traffic calming features, speed reduction policies, and provision of safe bicycle parking facilities at schools. Public awareness and traffic education campaigns targeting both parents and pupils are also part of the program. Despite these efforts and investments, the program has been only moderately successful in altering children's travel-to-school behavior and shifting children from cars to bicycles or walking (McDonald and Aalborg, 2009).

Active & Safe Routes to School. This is the Canadian version of the "Safe Routes to School" program. It was introduced in three Toronto schools in the mid-1990s, and later spread to more than 1000 schools in all Canadian provinces (Duggan et al., 2018). In 2006, the program was supplemented by "School Travel Planning", which expanded to more than 120 schools across Canada by 2012.

Active Travel Program. This program commenced in Northern Ireland in 2013. It largely targets primary schools, although secondary schools are also encouraged to participate. In participating schools, an "Active Travel Officer" is devoted to organizing a range of curricular lessons as well as extracurricular activities to teach children the benefits and risks of active commuting. The program has been successful in increasing the rate of active school commutes by 15% over a 3-year period. It has also led to a decrease in traffic congestion in the vicinity of participating schools (Duggan et al., 2018).

TravelWise School. This program commenced in New Zealand in 2002, and by 2014, more than 20,000 schoolchildren were involved within the Auckland region alone. The basic aim was to encourage school communities (including teachers, administrators, children, and parents) to take the lead in identifying local road safety problems and devise a complete plan for reducing traffic accidents and congestion (Morton, 2005). Thanks to TravelWise School, schoolchildren's car crashes rates have been successfully reduced and 12,000 car trips have been eliminated. Integrating "safe cycling and walking" lessons in the school curricula and securing the commitment of local police have been key ingredients to the program's success (Duggan et al., 2018).

School Travel Plans & ModeShift. Since 2003 the United Kingdom has been mandating all schools to develop "School Travel Plans." Funding to local authorities has been provided for this purpose, which has allowed schools to dedicate a special officer to the task of developing and promoting active travel plans. Overall, School Travel Plans have succeeded in reducing car use for the school commute, especially where combined with ModeShift. "ModeShift" is a measure to monitor school travel plans and their outcomes, which was initiated in 2007. As part of "ModeShift," an online "Sustainable Travel Accreditation and Recognition Scheme" was introduced, in which school travel officers could report progress, achievements, and failures (Duggan et al., 2018).

Your Move. This program was first established in 1995 in Perth, Australia, as "TravelSmart." The program ran for over twenty years, before the name was changed to "Your Move" in 2015 to align with other local initiatives. By 2013, 130 schools in Western Australia had been included in the program. Your Move operates on multiple fronts: it provides information, tips, and lesson plans via a website; it organizes campaigns and educational programs; it offers incentives and rewards to individual participants; and it provides infrastructure improvement grants to local councils. Your Move has enabled travel behaviour change among schoolchildren and in participating schools, car trips have dropped and active travel has increased (Duggan et al., 2018).

In 2020, the Covid-19 pandemic has had implications for active school travel. There is concern and some anecdotal evidence that active travel habits formed earlier may have been reversed or weakened. Unfortunately, due to fears around virus transmission in open spaces, children may be traveling by car more than before.

INTRODUCTION

Roger Vickerman

In an increasingly globalized world, despite reductions in costs and time, transportation has become even more important as a facilitator of economic and human interaction; this is reflected in technical advances in transportation systems, increasing interest in how transportation interacts with society and the need to provide novel approaches to understand its impacts. This has become particularly acute with the impact that Covid-19 has had on transportation across the world, at local, national, and international levels. This Encyclopedia brings a cross-cutting and integrated approach to all aspects of transportation from work in many disciplinary fields, engineering, operations research, economics, geography, and sociology to understand the changes taking place.

Transportation is both influenced by, and an influencer of, changes in the economy and society. Increasing speeds have reduced journey times and made the world a smaller place as globalization has affected both where people live and work and from where they source their goods and materials. Increasing volumes of traffic, often on old and life-expired infrastructure, lead to congestion and delays. Constraints on public budgets have led to increasing pressure on the private sector to fund improvements requiring new and innovative financial solutions. While there are clear differences in the nature of the pressures felt in the developed and less developed economies, there is an increasing recognition that in all societies, there is an accessibility problem such that certain groups become disadvantaged by the lack of access to reliable and cost-effective transport. While the problems are clearly multidimensional, research on transportation is often constrained by single disciplinary approaches and this carries over into the practice of transport planning and policy. The Encyclopedia cuts across these artificial boundaries by taking an approach that emphasizes the interaction between the different aspects of research and aims to offer new solutions to understand these problems. Each of the nine sections is based around a familiar dimension of work on transportation, but brings together the views of experts from different disciplinary perspectives. Each section is edited by an expert in the relevant field who has sought chapters from a range of authors representing different disciplines, different parts of the world, and different social perspectives. In this way, the work is not just a reflection of the state of the art that serves as a starting point for researchers and practitioners, but also a pointer toward new approaches, new ways of thinking, and novel solutions to problems.

The nine sections are structured around the following themes: Transport Modes; Freight Transport and Logistics; Transport Safety and Security; Transport Economics; Traffic Management; Transport Modeling and Data Management; Transport Policy and Planning; Transport Psychology; Sustainability and Health Issues in Transportation. Some of the chapters provide a technical introduction to a topic while others provide a bridge between topics or a more future-oriented view of new research areas or challenges. While there is guidance to cross-referencing between chapters, readers are encouraged to explore the tables of contents of all the sections to get a full understanding of the issues. Much of the Encyclopedia was completed before the Covid-19 pandemic and clearly this will have changed the situation in many areas covered by this work; the advantage of this type of reference work is that relevant updates will be possible in future editions.

The Encyclopedia has only been possible because of the cooperation of a large number of people. Robert Noland, Georgina Santos, Xiaowen Fu, and Dick Ettema served as an Editorial Advisory Board identifying possible editors of sections and advising on the overall structure. The Section Editors, Edoardo Marcucci, Kevin Cullinane, Per Garder, Maria Börjesson, Edward Chung, Chandra Bhat, Maria Attard, and Carlo Prato,

carried out the work of identifying potential authors of individual chapters, commissioning these, encouraging authors and reviewing drafts. More than 600 authors and co-authors of chapters are, however, are ultimately responsible for the success of this venture. Thanks are also due to the key people at Elsevier, particularly the Publishers, Andre Wolff and Oliver Walter, and the Project Managers, Sophie Harrison and Natalie Bentahar; they have shown exemplary patience over more than 3 years in bringing this work to fruition.

LIST OF CONTRIBUTORS TO VOLUME 7

Adelaide Cassia Nardocci

School of Public Health - USP, 715 Dr. Arnaldo Ave, SÃ£o Paulo, Brazil

Alireza Ermagun

Department of Civil and Environmental Engineering, Mississippi State University, Mississippi State, MS, United States

Amanda N. Stephens

Monash University Accident Research Centre, Monash University, Clayton, Australia

An-Magritt Kummeneje

Department of Civil Engineering, Kharazmi University, Faculty of Engineering, Tehran, Iran

Andrew Hill

CONTENTS OF ALL VOLUMES

<i>Editorial Board</i>	<i>v</i>
<i>Introduction</i>	<i>vii</i>
<i>Contributors to Volume 7</i>	<i>ix</i>

VOLUME 1

Introduction to Transportation Economics	1
Market Failures and Public Decision Making in the Transport Sector <i>Bruno De Borger and Stef Proost</i>	2
Demand for Freight Transport <i>José Holguín-Veras and Diana G. Ramírez-Ríos</i>	7
Cost Functions for Road Transport <i>José Manuel Vassallo</i>	13
Future of Urban Freight <i>Russell G. Thompson</i>	20
Operation Costs for Public Transport <i>Marco Batarce</i>	26
Natural Monopoly in Transport <i>André de Palma and Julien Monardo</i>	30
Freight Costs: Air and Sea <i>Yulai Wan and Dong Yang</i>	36
Transport Production and Cost Structure <i>Ricardo Giesen and Darío Farren</i>	46
The Concept of External Cost: Marginal versus Total Cost and Internalization <i>Sofia F. Franco</i>	56
Value of Time <i>John J. Bates</i>	67
Valuation of Carbon Emissions <i>Svante Mandell</i>	72
Valuation of Travel Time Variability Using Scheduling Models <i>Katrine Hjorth</i>	76

Value of Crowding <i>Daniel Hörcher</i>	84
What Drives Transport and Mobility Trends? The Chicken-and-Egg Problem <i>Nathalie Picard</i>	89
Pricing Principles in the Transport Sector <i>Bruno De Borger and Stef Proost</i>	95
Long-Run Versus Short-Run Valuations <i>Stefanie Peer</i>	102
Value of Noise <i>Jon P. Nelson</i>	106
The Value of Life and Health <i>Henrik Andersson</i>	114
The Value of Security, Access Time, Waiting Time, and Transfers in Public Transport <i>Raquel Espino, Juan de Dios Ortúzar, and Luis I. Rizzi</i>	122
Demand for Passenger Transportation <i>Kenneth A Small and Robin Lindsey</i>	127
Real-World Experiences of Congestion Pricing <i>Charles Raux</i>	134
Distributional Effects of Congestion Charges and Fuel Taxes <i>Jonas Eliasson</i>	139
The Bottleneck Model <i>Dereje Abegaz and Yili Tang</i>	146
Dynamic Congestion Pricing and User Heterogeneity <i>Kathrin Goldmann and Gernot Sieg</i>	150
Economics of Parking <i>Daniel Albalade and Albert Gragera</i>	159
Loss Aversion and Size and Sign Effects in Value of Time Studies <i>Andrew Daly</i>	165
Intertemporal Variation of Valuations <i>James Fox</i>	170
The Rebound Effect for Car Transport <i>Bruno De Borger, Ismir Mulalic and Jan Rouwendal</i>	174
Elasticities for Travel Demand: Recent Evidence <i>Fay Dunkerley, Charlene Rohr and Mark Wardman</i>	179
Parking Price Elasticities <i>Stephan Lehner</i>	185
The Pareto Criterion and the Kaldor Hicks Criterion <i>Harald Minken</i>	190
Social Discount Rates <i>Lars Hultkrantz</i>	195
Cross-Elasticities between Modes <i>Mark Wardman and Jeremy Toner</i>	201
First-Best Congestion Pricing <i>Moez Kilani</i>	209

Ethical Aspects-Can We Value Life, Health, and Environment in Money Terms? <i>Jose M. Grisolia and Ken Willis</i>	216
Car tolls, Transit Subsidies for Commuting, and Distortions on the Labor Market <i>Ioannis Tikoudis¹ and Kurt Van Dender¹</i>	221
Demand Management and Capacity Planning of Airports <i>Stephen Ison and Lucy Budd</i>	227
Dealing With Negative Externalities: Low Emission Zones Versus Congestion Tolls <i>Valeria Bernardo, Xavier Fageda, and Ricardo Flores-Fillol</i>	231
The Rule-of-a-Half and Interpreting the Consumer Surplus as Accessibility <i>Mogens Fosgerau and Ninette Pilegaard</i>	237
Producer Surplus <i>Chau Man Fung</i>	242
The Robustness of Cost-Benefit Analyses <i>Morten Welde and James Odeck</i>	249
The GDP Effects of Transport Investments: The Macroeconomic Approach <i>James Laird and Daniel Johnson</i>	256
The Mohring Effect <i>Hugo E. Silva</i>	263
Public Transport Fare and Subsidy Optimization <i>Qianwen Guo and Zhongfei Li</i>	267
Transportation Equity <i>Rafael H. M. Pereira, and Alex Karner</i>	271
Impact of Transport Cost-Benefit Analysis on Public Decision-Making <i>Niek Mouter</i>	278
Causal Inference for Ex Post Evaluation of Transport Interventions <i>Daniel J. Graham</i>	283
Transport Cost and Location of Firms <i>Adelheid Holl</i>	291
Commuting, the Labor Market, and Wages <i>Jan Rouwendal, and Ismir Mulalic</i>	297
How to Buy Transport Infrastructure <i>Johan Nyström</i>	302
Procurement of Public Transport: Contractual Regimes <i>Andrew Smith, and Chris Nash</i>	308

Introduction to Transport Psychology

Carlo G. Prato, School of Civil Engineering, The University of Queensland, Brisbane, QLD, Australia

© 2021 Elsevier Ltd. All rights reserved.

Transport systems are made of infrastructure (e.g., roads, bridges, stations, ports) and vehicles (e.g., bicycles, cars, trains, vessels), which most likely explains why economics and engineering have played an essential role in their study since the discipline known as transport engineering was born. However, transport systems are really made of people who use the vehicles on the infrastructure to become pedestrians, cyclists, car drivers, truck drivers, bus passengers, etc. This explains why transport psychology has been flourishing to answer questions about the people who populate transport systems from a behavioral, a cognitive and a social perspective. This also explains why transport psychology has been working toward helping provide answers from the transport demand perspective, in particular in relation to the role of attitudes and perceptions as latent concepts, and the safety perspective, in particular in relation to the role of hazard perception and driving behavior. The wealth of knowledge in transport psychology has certainly been flourishing also because of a wealth of methods that have become increasingly accessible in terms of psychological theories, methodological advancements and data collection techniques.

The articles in this section present the foundations of the discipline from theoretical, methodological and application perspective. All the articles provide a unique contribution to discovering the most compelling theories, the most appropriate data collection methods, the most innovative data analysis techniques, and the most popular issues up for debate. Extensive space has been dedicated to the collection of data, from the design of qualitative methods to the use of self-reports in a variety of contexts, culminating then in the use of the latest technology in driving simulator and naturalistic driving studies. Alongside data collection discussions, issues with their analysis have then been disentangled, starting from proper guidelines for qualitative analysis and statistical methods in traffic psychology, and arriving to models that integrate advanced econometrics with latent variable models that capture attitudes, perceptions, social influence, behavioral control, and all the elements of the most popular psychological theories. The focus of the section shifts then to key theories related to the demand side of behavioral studies, focusing for example not only on the affective and social aspects of choices, and the risk side of behavioral studies, concentrating on risky behavior such as speeding and hazards as well as their trigger such as distraction and aggression. Last, the focus of the section moves towards key issues such as vulnerable road users like cyclists and motorcyclists, educational and campaign programs for promoting wisdom (especially in young drivers), law enforcement theories for increasing safety, and perspectives on future mobility and the sharing economy.

Several of the chapters have cross-cutting themes with articles in other sections, from the closely related Transport Safety and Security to Transport Modelling and Data Management, from Sustainability and Health Issues in Transportation to Transport Policy and Planning. Readers are invited to explore these sections as well to have an even broader picture of the issues and fully appreciate the multidisciplinary nature of transportation studies.

From Self-Reports to Auto-Tech-Detect (ATD)-Based Self-Reports in Traffic Research

The Content and Situation of Self-Reports in Traffic Research

In recent decades, the popularity of self-reports in traffic research including the number of publications on self-reported traffic accidents (Kamaluddin et al., 2018) has increased drastically. Self-reports include a great variety of different methods including questionnaires and inventories, interviews, focus groups (e.g., Kua et al., 2007), and driving diaries (e.g., Joshi et al., 2001). As Lajunen and Özkan (2011) stated that common features in all these diverse self-report measures are that participants are aware that they are participating a study, they are asked to actively reply to more or less structured questions, and that their responses are taken “face valid,” that is, answers are scored and analyzed based on the responses and not, for example, according to response time or another behavioral or physiological measurement. In self-reports, the content of the responses in this way is assumed to reflect a respondent’s reality.

The Usage of Self-Reports in Traffic Research

Literature search shows that self-report methodology has been used for a great variety of research including attitudes, opinions, beliefs, emotion, cognitive processes, and behaviors—basically any aspect of driving. While acknowledging that self-reports can be the most appropriate tool or even the only tool for many research purposes (e.g., for measuring attitudes, beliefs, and opinions), self-reports have space to improve especially the self-reports of past accidents, near-misses, mileage, and road user/driver skills and behavior (Lajunen and Özkan, 2011).

Self-Reports in Driver Skills and Behavior

Although in literature self-reports have been used for measuring both driving skills (performance) and driving style (driver behavior), we can claim that self-report methodology fits better to studies of driver behavior than performance because of several reasons (Lajunen and Özkan, 2011). First, driver behavior refers to driving style, i.e. the everyday way of driving which driver prefers and drivers are mostly aware about. Drivers’ awareness of their driving skills can be assumed to be much lower, because the basic motor and perceptual processes are automatic and do not need attention (Lajunen and Özkan, 2011).

Second, driver behavior consists of behaviors, which are often included in Highway Code or unwritten norms. Because of this normative character of most of the driver behaviors, drivers actually know what the ideal normative behavior would be and can compare their behavior to those norms (e.g., try to drive just slightly above the speed limit). Opposite to driver behavior, it is usually difficult to determine the “skill norms” of driving and drivers are mostly unaware of their skill level. Because of these two issues, high awareness level, and the existence of an absolute norm, self-reports fit better to studies of driver behavior than driver performance (Lajunen and Özkan, 2011).

Some Paradoxes of Self-Reports in Driver Behavior

The paradox in self-reports of attention or memory mistakes is that most of the errors go unnoticed (Lajunen and Özkan, 2011). As Bjørnskau and Sagberg, (2005) accurately pointed out: "Unconscious errors may be hard to remember precisely because they are unconscious." We can assume that drivers (e.g., elderly drivers, drivers with slight dementia) prone to cognitive failures and forgetting while driving have also difficulties in remembering their mistakes when answering self-reports like Driver Behavior Questionnaire (DBQ). In addition, asking "violating drivers" to honestly report their violations is the second paradox in the DBQ and self-reports in general: we assume that people who like to violate social norms in traffic would respect the honesty required in self-reports. It is more likely that drivers who do not respect general rules and norms in traffic would also not be exactly honest when answering self-report surveys (Lajunen and Özkan, 2011).

Self-Reports in Self-Assessments

Drivers' views of their skills can be studied with self-reports but direct measurement of real driving skills with a self-report is almost impossible (Lajunen and Özkan, 2011). Driver Skill Inventory (DSI) (Lajunen and Summala, 1995) provides another example of measurement of driver skills with self-reports. However, DSI does not actually even pretend to measure skills but rather a driver's skill and safety orientation. Drivers are asked to evaluate themselves as drivers by indicating their strong and weak sides in driving. Hence, the external criterion (compared to "other drivers") or absolute criterion (frequency of errors) was replaced by internal comparison. Direct measurement of driver skills or errors is very difficult and possible unreliable with self-report instruments. However, self-reports can be used reliably to measure a driver's view or opinion about his or her skills. While remembering individual mistakes is difficult, drivers are usually having a general idea of themselves as drivers, which can be measured by self-report instruments (Lajunen and Özkan, 2011).

Self-Reports in Accidents, Near Accidents, and Mileage

While self-reports are not adequate measures of unconscious processes or norm violations which drivers would not like to report honestly, self-reports work well when recording driver attitudes, self-evaluated skills, and beliefs. Interestingly, most of the self-reported drivers' behaviors are evaluated in terms of how risky they are, that is, the potential in causing a serious accident. Hence, accident risk seems to be the ultimate criterion for driver behaviors and, therefore, either objective or self-reported number of past accidents is used as a criterion for safe driving (Lajunen & Özkan, 2011).

Accidents

In most studies concerning behavioral correlates of individual differences in road-traffic accident risk, a driver's accident history (number and/or the severity of accidents) has been used as a criterion for safety. This accident data is collected either from drivers' self-reports or from the official statistics. However, both are subject to systematic and random error and are, therefore, somewhat biased (Elander et al., 1993). The advantage of asking drivers to report accidents is that minor crashes can also be recorded. In addition, driver's self-reports are usually more detailed than official reports, since drivers can be asked very specific questions. However, comparisons between self-reported and state-recorded numbers of accidents have shown some under-reporting of accidents in self-reports (Lajunen and Özkan, 2011).

Self-reports of accidents are easily biased by intentional or unintentional misrepresentation (Elander et al., 1993). The latter source of bias can be caused either by a different definition of reportable accidents between drivers or by simple forgetting. Chapman and Underwood (2000) concluded that "there is reason to suspect that even severe accidents may be routinely forgotten by normal drivers over periods as short as a year." They also suggested that minor accidents are forgotten at much higher rates. While self-reports of accidents seem to be more or less problematic and the degree of accuracy seems to depend on various factors (e.g., time period, age of the participants, way of conducting the survey), official accident records from the police, hospitals, or insurance companies seem to have many shortcomings too. Forgetting, various definitions of accidents or deliberate under-reporting typical to self-report do not distort the official accident records, but official records have some other limitations. First, the police or insurance companies' accident records do not include minor damages, and secondly, some driver groups, like older drivers, can be over-represented in these records for reasons not related to their risk of accident (Elander et al., 1993).

In addition to the age and gender bias as well as not including minor accidents, official accident records are not always available because of data protection acts and because the period of accidents recorded might be limited. Also, the type and role of the parties (e.g., culpability) in the accident are rarely available. Studies about self-reports of accidents and state records show that both recording methods have considerable shortcomings and strengths. As a conclusion, it seems that the best self-report method for recording accidents is a retrospective self-report of maximum of 5 years. Shorter the reporting period is, smaller the underreporting bias due to forgetting should be. If possible, self-reports should be complemented with state accident records (Lajunen and Özkan, 2011).

Near Misses

Since the forgetting rate gets higher when the time period for recall gets longer and when minor accidents are asked, we could suppose that self-reports of serious accidents, say, in the previous year would be the best estimate. However, accidents and especially serious accidents are (luckily) infrequent. This means that samples in accident studies should be enormous, which in turn, is

impossible for most of the studies. One approach to this problem is to record near-accidents, which are extremely frequent events (Chapman and Underwood, 2000) and may lead to a crash in less optimal conditions. By definition, near-accidents can be assumed as a good candidate for a general measure of safety.

Chapman and Underwood's (2000) study shows that while near-accidents are very frequent and, thus, easier to use in statistical analyses than actual accidents, the high forgetting rate makes them an unreliable measure of risk. Near-accidents can best be recorded by using driving diary technique, in which drivers keep a log about their near accidents for a couple of weeks. Since near-accidents are recorded as soon as possible after they have happened, the forgetting rate stays low while the number of near-accidents is much higher.

Exposure

Mileage is one of the main factors measured in studies about driver behavior. Mileage as total life-time mileage or annual mileage and type of exposure are extremely important variables, because mileage (and exposure) largely determines a driver's likelihood of being involved in an accident. Moreover, particular driver characteristics may lead only to particular forms of driving behavior which may, thereby, affect liability only for accidents of certain types (Elander et al., 1993).

The effects of mileage on driving style and accidents depend largely on the type of exposure. Type of roads usually driven (motorways versus country roads, traffic density), time of year (winter versus summer) and day, time of the day spent on the road (daylight versus night), and usual purpose of driving (work-related versus free-time) all affect the likelihood of accident involvement and driving style. Special effort should therefore be directed to measure these factors related to exposure in studies on driver style and accident involvement, since exposure may be related to psychological variables under investigation. Ignoring the role of driving experience and exposure can increase error variance and reduce the true associations between psychological variables and accident frequency (Elander et al., 1993).

In driver behavior studies, mileage is traditionally measured with either driving diaries or questionnaires, which both are based on self-reports. As self-reports, self-reports of mileage share in some degree the same problems and bias sources as self-reports of accidents. The accuracy of self-reports has been questioned in several studies, and in-vehicle recording devices have been suggested as an alternative to self-reports (Blanchard et al., 2009). While in-car recordings certainly provide a more unbiased and accurate measure of exposure than self-reports, their usefulness is still very limited to certain types of studies. For example, large-scale population studies do not allow direct recordings of driving frequency and amount. Moreover, many studies require anonymous participation and, thus, direct measurements cannot be considered.

While mileage self-reports share some of the problems with self-reports of accidents, for example, drivers forget to report some trips, we can assume that self-reports of mileage are less biased than self-reports of accidents because of several reasons. An accident is a single event but the estimation of mileage is continuous, which makes it naturally easier to evaluate. While accidents can be embarrassing or even traumatic events which one would like to forget, mileage is a rather neutral issue. Moreover, there are more techniques for reporting exposure than accident involvement: drivers can be asked to report their lifetime mileage, mileage in a certain period of time (year, months, week, day), frequency of driving in days or number of trips in addition to the type of exposure (e.g., in-city traffic, highways, night driving). Drivers can also be related to their life-time mileage to other more objective measures like ownership and use frequency of their car (Lajunen and Özkan, 2011).

Memory and Social Desirability

According to Chapman's and Underwood's (2000) study about forgetting near-accidents, about 80% of incidents were no longer reported after a delay of up to two weeks (Chapman and Underwood, 2000). Surprisingly, experimental studies about the effect of socially desirable responding (self-deception or lying) show that the social desirability bias is not a considerable problem in the Driver Behavior Questionnaire responses (Lajunen and Summala, 2003; Sullman and Taylor, 2010). Still, future users of the self-report measures should bear in mind that forgetting and socially desirable responding are potential sources of bias in driver behavior (Lajunen and Özkan, 2011). These biases might interact with sample characteristics, which means that forgetting and socially desirable responding is more pronounced among certain driver groups. The best way to reduce the bias related to forgetting and socially desirable responding is to use the DBQ always as an anonymous research instrument and not for evaluating individual drivers (Lajunen and Özkan, 2011).

Impression Management and Self-Deception in Self-Reports

A large number of studies involving different measures of socially desirable responding have shown that it consists of two distinct factors which can be called "impression management" and "self-deception," or in other words "other-deception" and "self-deception" (e.g., Paulhus, 1984). In this distinction, impression management refers to the deliberate tendency to give favorable self-descriptions to others and comes, therefore, close to lying and falsification (e.g., Paulhus, 1984). The deliberate nature of impression management is also manifested in the finding that impression management increases in public settings and seems to be a situation-dependent phenomenon (Paulhus, 1984). It has been recommended that impression management should be controlled when it is conceptually independent of the trait being assessed but still contributes to the self-reported scores of that trait (Paulhus, 1984; Paulhus and Reid, 1991).

The self-deception factor can be characterized as a positively biased but subjectively honest self-description. In contrast to impression management, self-deception is an unintentional tendency and not influenced by the anonymity versus public context

manipulation (Paulhus, 1984). Unlike impression management, self-deception has been reported to be intrinsically linked to positive personality constructs such as psychological adjustment like high self-esteem (Paulhus and Reid, 1991). These findings suggest that self-deception could be used for the purposes of gaining pleasure (ego enhancement) as well as avoiding pain (denial) and, therefore, provides aid for coping with negative life events and threatening information (Paulhus, 1984; Paulhus and Reid, 1991). Self-deception appears to be more of a personality construct than simply a distorting factor. Paulhus (Paulhus, 1984; Paulhus and Reid, 1991) suggests that self-deception should not be controlled if it is an intrinsic aspect of the personality construct concerned. It should be noted, however, that the bias caused by self-deception may not be constant over situations. Some situations can be more threatening than others and, therefore, elicit a stronger need for self-deception.

Coping with Socially Desirable Responding in Self-Reports of Driving

One possibility is to give up using self-reports of driving and accidents and to rely only on observed behavioral data and official accident records as some researchers seem to suggest (AfWahlberg et al., 2009; AfWahlberg, 2010). However, the objective measures have serious methodological limitations too as studies using an instrumented vehicle, simulator or laboratory tests show. Official accident records suffer their own sources of bias too (Lajunen and Özkan, 2011). The other possibility is to let them the use of self-reports of driving to go unchallenged and accept the small social desirability bias as innate characteristics of self-reports. Self-report research methodology offers various ways of coping with socially desirable responding. First, emphasis on anonymity and confidentiality in instructions and procedures (e.g., sealed envelopes, large group data collection) all reduce the effect of socially desirable responding. Second, scales for socially desirable responding like DSDS can be added to studies and their effect statistically controlled. Scales for controlling impression management, self-deception, careless answering style etc. can be easily be designed and embedded to such instruments as the Driver Behavior Questionnaire.

Future Directions and/or Corrections: Auto-Tech-Detect (ATD)-based Self-Reports in Traffic

It is well-known that cars already consist of different types of in-vehicle technologies that can be used for collecting driver's information while driving. Besides, Global Positioning System (GPS) devices including smartphones provide measures of driving exposure or travel patterns. It is possible that self-report bias in mileage estimate can be best solved by not using self-reports but rather relying on, for example, GPS based in-car recordings. Since this is not possible in many survey studies, the best remedy for reducing self-report bias is to use as many estimates of mileage as possible. For example, total annual or monthly mileage, frequency of driving (number of trips per time unit) or proportion of long trips can be asked and the final estimates can be based on several self-report indicators (Lajunen and Özkan, 2011). Such a combination of ATD based and pure self-reports allow researchers and practitioners to more easily compare and/or combine self-reported and ATD-based travel-related behavior. Furthermore, autonomous vehicles are on the way of travelling on roads at different levels of autonomy collecting, monitoring, controlling data, and behavior.

We can claim that, thus, diverse self-report measures tend to change its focus (i.e., data collection method, sample size, age of respondents, user type of respondents, recall period, follow-up precision and data quality, and ways of data collection—recruitment vs anonymity) while ATD based self-reports supply new advantages such as comparability with other data, reduction of desirability bias, precision at response rate, road user characteristics and outcome measures (e.g., Kamaluddin et al., 2018). As a result, participants are implicitly and/or technologically aware that they are not only participating in a study but also a participative complementary element of measures of driving. They are implicitly and/or technologically “asked” to actively reply to more or less structured questions or rather conditions, and that their responses are taken “technologically pin valid,” that is, answers are scored and analyzed based not only on the responses but also, for example, according to response time or other behavioral or physiological measurement. In ATD based self-reports, the content of the responses in this way is not assumed but counted as to reflect a respondent's reality.

It can also be claimed that some paradoxes based on social desirability, attention capacity or memory losses, and others of self-reports in driver skills and behavior may be solved by the support of ATD based self-driving capacities. Besides, direct measurement of driver skills or errors can be possible with reliable ATD based self-report instruments and general or holistic view of driver skills can be calculated by developing new indexes including both ATD and pure self-evaluations on attitudes, beliefs norms, and capacities.

In other words, ATD based data will strengthen “what” parts of behavior and skills and even accidents because we will have more precise measures and data sets. Ironically, “why” parts of behavior and skills and even accidents may go more center of traffic studies. Thus, “pure” self-report measures may be even more critical into some extent. Norms, time, and context including traffic culture/climate (e.g., Özkan and Lajunen, 2015) seem to be embedded or anchored to behavior and skills or even accidents to some extent.

Özkan et al. (2019), for instance, measured self-reported seatbelt use, observed use among those who self-reported was compared with observed seatbelt use in the two city populations. They found that an increase in population-based observed seatbelt use rate among drivers both in Afyon and Ankara was also reflected in the increase in self-reported use rate, and the observed rate among those who self-reported. Over reporting in self-reported use rate decreased over time, however, the statistically significant difference with population-based observed rate existed over time. In other words, the self-reported seat belt use among individuals might be anchored to the general usage rates in the population.

Özkan et al. (2006) interpreted changes in DBQ factor structure by the classification of alpha, beta and gamma (Golembiewski et al., 1976). ATD-based data and/or responses and “pure” self-reports may need to be evaluated separately or together in this direction in this new phase of traffic research. Golembiewski et al. (1976) defined alpha change as a change, which “involves a variation in the level of some existential state, given a constantly calibrated measuring instrument related to a constant conceptual domain.” Alpha change represents an unbiased measure of variation between Time 1 and Time 2 in the observed phenomenon (e.g., less competitiveness between T1 and T2). According to Golembiewski et al. (1976), beta change is characterized by “a variation in the level of some existential state, complicated by the fact that some intervals of the continuum associated with a constant conceptual domain have been recalibrated.” It refers to an observed variation in some state where the apparent change is due to an instrument that has been recalibrated by the participant between assessments (e.g., adaptation to risk). By Golembiewski et al. (1976) definition, gamma change “involves a redefinition or re-conceptualization of some domain, a major change in the perspective or frame of reference within which phenomena are perceived and classified, in what is taken to be relevant in some slice of reality.” Golembiewski et al. (1976) showed that gamma change might be indicated through a comparison of factor structures over time. In addition, both alpha and beta change should be taken into account when comparing factor structures. It is possible that some drastic events (e.g., involvement in a traffic accident) may change a driver’s view (“pure” self-reports) of driving or driving itself (ATD-based responses) and traffic safety in general. Interdependency between some variables, Characteristics, road user types, etc. should also be examined as possible reasons and types of change in reporting or responding in traffic.

Of course, these possibilities can open a new phase about reliability, content, construct, and criterion validity or predictive validity issues of self-report measures in traffic research. Sure, this may require researchers and practitioners to have more comprehensive models and/or theories of a road user/human or ATD based data behavior. The problem may not be the lack of reliable and valid data rather rich in data or the lack of powerful and real models of humans on roads. As stated by Bailey and Wundersitz (2019), carefully defining terms (e.g., crashes); assuring confidentiality of responses; identifying individuals who erroneously believe inappropriate driving behaviors such as speeding are really quite safe; considering the use of pre-determined response categories (e.g., 1–2 times a week); and considering having a control group not exposed to a campaign or other intervention can be critical for reducing noise in data collection and modeling phases. Finally, data protection laws and/or regulations may also draw the lines of a new phase of the combination of “pure” self-reports and ATD-based ones in traffic research.

Conclusions

When evaluating the role and evolution of self-reports in traffic research, we still fully agree with Reason et al. (1990) that the tool (i.e., like DBQ) is a powerful means to measure behaviors that are “too private to be detected by direct observation” but that at the same time “DBQ responses are several stages removed from the actuality of what goes on behind the wheel.” The same applies to self-reports in general: they are able to reveal information which is not available with any other measurement methods. The gap mentioned by reason between the reality and the picture given by self-reports may not be possible to erase but at least it can be considerably shortened with adequate use of self-report methodology and the advance support of ATD-based data and responses.

Introduction

Research in traffic psychology relates to investigation of various human behaviors of road users such as drivers, passengers, pedestrians, bicyclists, motor bicyclists and others. This chapter is aimed to review studies which are based on elements of observational methods and will examine how each method is closer than nonobservational methods to real-life behavior of road users. Overall, research in traffic psychology can be sorted by proximity (or distance) to authentic behavior. The farthest method is using questionnaires. This method is a popular way for measuring attitudes in regards with unsafe behavior such as traffic violations that imply on the people's behavior. Indeed, theories like PBT (Ajzen, 2011) try to measure the variables that mediate between attitudes and real behavior (e.g., perceived norms, perceived control, and behavioral intention). As to behavior measured by questionnaires, using self-report questionnaires (e.g., DBQ—Driving Behavior Questionnaire, Reason et al., 1990) is a well-established method to examine how people behave on the roads.

Studies based on simulations of on-road situations (computerized or by simulators) try to get closer to real behavior by studying road users' behavior in simulated situations. Mostly, the validity as well as the reliability of these methods are high. However, it is still likely that people would react differently in real-life situations. Other studies measure people's reactions in labs (experimental studies). Lab studies can be well-designed and control all the “noisy” variables. Such studies enable the researchers to measure precisely the behavior by objective parameters rather than by estimation. The problem with these studies is that they do not reflect the reality and ignore situations that may intervene between the lab and the real-world situations.

Naturalistic observations are focused on people's behavior, including drivers, pedestrians, and vulnerable road users acting in traffic environment. The studies based on this type of research document the behavior that happens here and now. If well-designed and conducted “by the book”, this genre of research is better than others due to its directness. It does not examine what people are thinking about their behavior, what is their attitude regarding it or what they report about themselves. It simply examines real behavior. In addition, naturalistic observations happen in the real settings rather than in labs or in simulated situations, so we can realize how people really behave in everyday life situations (e.g., Riaz, 2016)

Naturalistic observations have weaknesses as well. Generalizability is one of the problems, because we cannot be sure that the people behave the same in various locations. This may be solved by quantity (observing huge numbers of road users) and variety (various locations, various time of the day, etc.). Data collection might be also problematic, due to subjective estimation of the observers. For that reason, researchers should put an emphasis on good training for their observers. Another solution for this issue can be using electronic devices in order to collect data more objectively and accurately.

Hence, field studies (expanded later) try to combine the advantages of both lab experiments with observations. For example, Zivotofsky et al. (2012) compared the estimated road crossing time as pedestrians of young and elderly individuals. It included precrossing estimation and measuring the actual time it took them to cross the street. Following the actual street crossing pedestrians were asked to estimate the time it took them to cross the road.

Studies Based on Existing Databases

An optional way to relate to data of road users is analyzing big data bases. This includes demographic details, data of traffic violations (e.g., Rosenbloom and Eldror, 2013), drivers' performance on-road (Flannagan et al., 2019), using smartphones while driving in trucks (Hickman and Hanowski, 2012) etc. SHRP 2 Naturalistic Driving Study (Wu and Xu, 2017) is a good example for a large database of naturalistic driving that documented 300 travels and analyzed different aspects of safe driving. This study was based on video clips of the road as well of the drivers' faces. It examined the influence of some external factors on the drivers' behavior and

concluded that the vehicle type, the traffic flow, pedestrians, and drivers' age were the most crucial for explanation of drivers' behavior. In another study, a different group of road users was studied: Hussein et al. (2015) analyzed pedestrians as well as drivers' behaviors in signalized intersections in order to predict future intentions of pedestrians in relation to other road users' action.

Rosenbloom and Eldror (2013) compared police records of 1549 impounded drivers with 1354 controls regarding their matching violations performed prior to the application of the impoundment regulation, comparing accident and traffic-violations involvement in the subsequent year. This has been made in order to examine the effectiveness of vehicle impoundment system as a punishment.

The above-mentioned studies were based on analyzing existing databases. As a matter of fact, these studies were based on data of real behavior, but they still do not investigate behavior directly. The next section deals with direct observations of road users' behavior.

Controlled Observations

Usually, studies in traffic psychology deals with topics such as yielding of drivers to pedestrians, dilemma zone or amber light dilemma, safe road crossing of pedestrians, drivers' risky behavior, and road users' distraction. Observations are made with or without controlled interventions. The following studies have been conducted with interventions. Michael et al. (2000) examined the effect of signs shown to drivers on tailgating while driving at urban roads in normal traffic hours. The observations that have been taken along 10 weeks were recorded by video cameras. At certain places, a sign of "Please don't tailgate" was held by an experimenter and at other places another sign of "help prevent crashes please don't tailgate" was held. The different signs yielded different reactions of drivers and all reactions were recorded. Tailgating was measured by seconds of getting to the first vehicle.

The following study has been based on a rather complex design: Bertulis and Dulaski (2014) conducted a sophisticated design of their study. The purpose of this study was to measure how driver speed affects the rates of yielding for pedestrians. The study was designed to be "staged" with the exact same pedestrian for each driver and have the exact same amount of time to react and decide whether they would yield or not. The observer had a hand-held speed radar gun and a notebook to record the number of yields during attempted crossing events by the person. The study was conducted on the basis of the selective method, meaning the pedestrian (an experimenter) steps into the street as a driver is approaching, but with enough time for the driver to notice and brake. The observer first used the radar gun to measure the speed of at least a dozen vehicles and obtain the 85th percentile speed. Then, only the free-flowing vehicles going within two mph of the 85th percentile speed were recorded. All the locations had the same features regarding the geometry, lane configuration, parking of vehicles and surrounding land use.

Nonetheless, controlled observations have been made not only to study interaction between different road users but also to see how people manage with dual task on the roads. In order to test how smartphone tasks are associated with inattention blindness of pedestrians while crossing the street. Chen et al. (2016) designed a study that combined both field experiment together with interviews. All in all, 2556 pedestrians crossed the street and underwent the interview and were sorted to distracted and nondistracted pedestrians. This was determined by cameras' records. In addition to demographic details that have been collected through the interviews, inattention blindness and deafness were tested by placing a clown walking by them playing the national anthem. The two groups of pedestrians were asked if they noticed something unusual in their surroundings.

In line with the previous study, another field experiment was designed by Rosenbloom (2006) for the purpose of studying the effect of talking with cell phone while driving on speeding and safe gap keeping. The study was based on observations made by a passenger sitting by the driver through spontaneous driving. The manipulation made by the researchers was initiating two phone calls during the travel to which the drivers responded and talked along the travel. The observers sampled two different periods to register: 10 min during conversation and 10 min of nonconversation and compared the speeding and gap keeping behaviors of the drivers. After the travel, the drivers were asked if talking on phone while driving is disturbing.

The study combined spontaneous manipulated observations on pedestrians as well as personality and demographic questionnaires (Rosenbloom, 2006). Students were observed by crossing a signalized intersection (in green or red light). After reaching the other side of the intersection they were asked to participate in a survey that included Sensation Seeking Scale V (SSS; Zuckerman, 1994)

and demographic details. The study was carried out in four conditions: with or without the presence of a policeman and hurrying or not hurrying. The associations of the presence of the policeman, the time, the level of SS with the crossing (in green or in red) were examined.

Uncontrolled Observations Field Experiments (Field Studies)

Unlike controlled observations, uncontrolled observations do not involve any manipulations or interventions of the researchers. Observation means (human observers or video cameras, etc.) are placed in the location of observation to monitor the behaviors of the road users. The advantage of unobtrusive observations over other data collection methods is that people behave more spontaneously and in an authentic way when they are not aware of being observed. This may increase the validity of the study. This chapter makes a distinction between "human" observation and electronic devices which collect data such as video cameras, eye tracking systems and physiological monitoring equipment. For instance, in order to study factors that affect signaling rate on the road, researches placed human observers in junctions to record of 5600 vehicles. Observers used a chart to tick behaviors such as: the

direction of turn, whether the driver signaled or not and how the signaling was done (Faw, 2013). In a similar way, Rosenbloom et al. (2009a, 2009b) conducted a study to examine how often drivers commit driving violation based on the type of location they drive (i.e., city, town, or a village). The researchers examined five different type of violations: seat belt, safety seat for a child, using a phone without a speaker, give-way sign, and stopping in an undesignated area. Trained observers recorded, using a grid- observation, drivers in their natural environment to see which location are characterized with the overall highest rate of driving violations.

One interesting way in observational field studies is to accompany drivers and track their behavior without their knowledge. The present study aimed to do that and to examine the effects of road familiarity on driving performance. Observers joined female drivers for a trip drive as their friends. Drivers were not aware of their participation in the study. The observations were performed on a sample of different drivers who were driving on similar routes in terms of road quality, traffic volume and other road conditions. The more and the less familiar road sections had similar infrastructural and environmental characteristics. In order to mask the observation, the observers told the drivers that they had to complete some paperwork. Each participant drove in two conditions. A familiar condition, operationally defined as the drivers' residence towns and the nearby areas. Less familiar condition, operationally defined as other towns. At the end of the drive, the observer talked to the driver about the amount of tickets she received, average driving distance per month and license seniority (Rosenbloom et al., 2007).

Other studies used observations on pedestrians. A study that aimed to trace crossing behavior of pedestrians compared two groups: individual pedestrians and groups of pedestrians. Observers examined whether or not pedestrians crossed at a red-light and to what extent it happened in each of the research groups. Observers recorded variables like date, estimated age, gender, traffic volume, and durations of the green light using an observational grid (Rosenbloom, 2009).

Some observational studies examine specific populations among pedestrians. For instance, military officers are expected to show more compliance with the rules. Hence, Rosenbloom (2011) checked how values such virtue, honor, patriotism and subordination, which are often expected from officers, are exhibited when they crossroads compared to soldiers and civilians. Six parameters defined a safe crossing and the officers or soldiers were recognized by their uniforms. Close to an army base, and in the center of a city, observers registered the behavior of pedestrians in similar conditions like location, time and traffic volume.

Another example of specific populations is examining gender differences on driving and walking. Four crossroads for pedestrians were chosen. Observers watched all behaviors of both genders, using an observational grid which describes the whole processes of crossing. This study was part of a bigger research aimed to model pedestrians' behaviors. The experimenters stood on the opposite sidewalk, so they could easily check where a pedestrian was looking. The experimenter was equipped with a digital camera with a voice recorder and orally noted the pedestrian behaviors according to the observation grid. Experimenters learnt all behaviors by heart in order to record behaviors faster (Tom and Granié, 2011).

Pedestrians are sometimes involved in accidents because of their own technological or social distractions. Observers recorded pedestrians talking on the phone or to another person or holding hands during crossing the road. The researchers aimed to study to what extent these behaviors affect the duration of the crossing, violations of signs and looking at both sides of the road. Observers had a timer to check the duration of crossing and used a special table, prepared in advance, to record the behaviors (Thompson et al., 2012).

Often, observational studies look at various types of populations at the same time to compare their behaviors. This happens when researchers want to see how one behavior affects the safety of the people on the road. One of these studies compared the behaviors of pedestrians crossing the road with or without using the phone. Observers had an observational grid to record all information. They had both details about demographics and type of behavior, and they had a control group to compare how long it took them to cross the road (time matched control) and their demographics (demographic matched control; Hatfield and Murphy, 2007).

Another research studied pedestrians from a different perspective. The study looked at the connection between violation of pedestrians and motor vehicles in traffic light intersections and the rate of collisions between pedestrians and motorized vehicles. The method (GIS method) included recognizing dangerous junctions and in terms of accidents' rate and recording of the violations (Cinnamon et al., 2011).

The following study focused on the effect of religion on pedestrian behavior. The aim was to investigate the differences between religious and nonreligious pedestrians in urban intersections in two cities: one secular and one ultra-orthodox. Observers looked at behaviors such as running a red-light, crossing where there is no crosswalk, walking along the road, failing to check for traffic prior to crossing, and taking a child's hand when crossing. Three observers observed different groups: children, adults and total number of pedestrians crossing (Rosenbloom et al., 2004). Furthermore, the authors of the previous study were interested to reveal if the phenomenon of ultra-orthodox pedestrians appear solely in ultra-orthodox places. The following study used on observation grid to look at ultra- Orthodox and secular pedestrians in neighboring ultra-orthodox and secular cities. The crosswalks observed were similar to each other and the aim was to track the tendency to cross in a red light. Four trained observers watched the followings: observing children and young pedestrians, observing adult pedestrians, observing elderly pedestrians and last two observers were responsible for tracking the total number of pedestrians crossing the road and the total number of vehicles passing by, respectively (Rosenbloom et al., 2008a,b).

Not only adult pedestrians were in the focus of researchers who made observations. The following study depicted behaviors of children crossing a crosswalk. Two hundred sixty-nine children were observed between the ages of 7–11 near to an elementary school. Some children crossed with the help of an adult and some did not. Unsafe behaviors such as not stopping at the curb, not looking before crossing, attempting to cross when a car is nearing and running across the road were noted. Observation took place on hours that children usually go to school at three similar intersection. The study question was whether and how an accompany of an adult change the road crossing behavior of the children (Rosenbloom et al., 2008a,b).

Electronic Observations

Unlike human observation that is based on trained observers that record people's behavior, electronic observations rely on cameras that are placed either on the roads or in the drivers' car or other electronic systems that can monitor the road users' actions and/or other parameters on-road. One of the first and the most famous study of Naturalistic driving was conducted in the United States with equipped 100 cars were observed (Klauer et al., 2006) for a year. The researchers were interested in the information inside and outside the cars before an accident (or near to accident) occurred.

A study by Tivesten and Dozza (2015) observed drivers to examine, which factors lead to engagement of drivers in visual manual phone activities. The study aimed to answer questions such as: which contexts affect the tendency to be involved in phone activities, which contexts affect the timing of use on the phone and whether self-regulation increase the safety margins of drivers. The researchers collected information from 100 Volvo cars, which was part of a bigger project of EuroFOT using naturalistic driving data, and accompanied them for a year. The cars were driven in real traffic by the main drivers and other household members. The drivers all lived in the same area. No advanced driver assistance system was activated during the first 3–4 months of driving, which is the data used for the study. Researchers used cameras, sensors and other devices to collect the data. The data collection covered travel in its entirety, that is, from the moment the engine started until it was switched off. Though study has not met the full criteria of naturalistic observation (since the drivers were aware that they were observed all the time), drivers were still in their natural environment of driving. Other studies were aimed to look at main risk factors happen right before an accident. Specifically looking at the moments before it happened. Dingus et al. (2016) analyzed collision situations using of video recorder measurements of 3542 drivers that were recruited to SHRP 2 NDS system. The study categorized three age groups and specifically examined drivers under the age of 25 and above the age of 65 which are the ages in which most accidents occur.

In some cases, observations are taken in order to reveal what are the psychological circumstances that yield anger of road users. Precht et al. (2017) examined the correlation exists between anger and accidents and tried to look for the causes- whether it is because aggressive driving or because cognitive load. The study used SHRP2 records and analyzed 10 min videos when drivers were caught angry and the driving violations or mistakes they did through this time. They created behavioral factors to look at and watched which of these behaviors happened in a way that they could conclude for the reason behind the violations or mistakes in driving.

Distraction of drivers is often studied through experimental procedure but also by naturalistic observations. Wu and Xu (2018) conducted a study that looked at the connection between road familiarity and doing secondary task which are a cause of distraction. The reasoning for using naturalistic driving data is because it is hard to collect data about distractive activities like eating, putting on make-up and so on during driving simulations on a lab. The researches define a familiar road as one that drivers pass through at least once a week, and not familiar as one that driver pass through once a year.

Integration of Methods in Observational Field Studies

In order to gain the advantages of naturalistic observations on the one hand and of self-report techniques on the other, some studies combine naturalistic observations with other procedures such as simulations, questionnaires, etc. A combined method of both observations and questionnaires was used to study pedestrians' behavior when crossing the road and their perception of the walking environment before and after installing a marked crosswalk. Researchers examined the crossing behavior 14 months before the crosswalk was installed and after 6 weeks after its installation. Observation was video-based, and questionnaires were conducted consecutive to the crossing, so the sample of the observation and the questionnaires would be similar (Havard and Willis, 2012).

Rosenbloom and Pereg (2012) adopted this trend and examined how long pedestrians wait before crossing the first, the second and the third road divided by an island. The authors hypothesized that though in a narrow island there would be a negative correlation between the first and the second crossing and the waiting time, in a wide island the correlation would be positive since pedestrians perceive the wide two-stage crossing as isolated units. The research integrated two methods: an observational experiment and a questionnaire. Two trained experimenters managed the research. One observer recorded with a stopwatch the waiting time of the pedestrians from the first to the third crossing, checking how long it took the pedestrians to cross each unit. Then, the experimenter noted the information in the observational grid. The second experimenter stood at the end of the third crossings with a questionnaire to ask pedestrians for their demographic details. Only pedestrians who agreed to participate in the research by answering the questionnaire were included in the sample.

A unique study was conducted by Pantangi et al. (2020). This study examined the influence of High Visibility Enforcement Programs (HVEs) on diverse types of aggressive driving behavior, that is, speed, failure to maintain distance and dangerous lane change. Researchers asked whether using such a program reduces aggressive behavior on the road. The study used SHRP2 and NDS. The uniqueness of this study is the development of graded indices to compare the intensity and time period of speed and failure to maintain distance when different levels of aggressive behavior should be perceived. First, a campaign was conducted to inform the residents of the selected areas about the existence of the enforcement plan. Second, road cameras were hacked to track behavior and police officers carried out enforcement.

Signal detection theory is known as a paradigm that is appropriate for studying in labs. Rosenbloom and Wolf (2002b) translated this paradigm to terms of naturalistic behavior. In this study, the researches aimed to ask how the signal detection paradigm can serve to examine drivers' decisions in life traffic dilemmas. Observers joined a driver, with their awareness and permission, as silent passengers. The observers joined the drivers for their driving every day for three to four weeks. All drivers filled sensation-seeking and

demographic questionnaire. Observers were recruited based on their personal interview and filled an approach to driving questionnaires to minimize any of their biases. Only observers that were found to be innocent and well-balanced decision-makers on the road were recruited. The same researchers tried to test drivers for sensation seeking by computerized simulation and responding to it. The study was constructed of three experiments. In each experiment participants were exposed to road dilemma (either by a simulation, or in reality or acting it by themselves). The decision they had to make was always binary: to do or not to do (Rosenbloom and Wolf, 2002a).

Traffic Conflict Technique is an alternative method to analyze statistics of accidents. A conflict situation is when two road-users arrive each other at the same time and space, so if their movement stays unchanged, an accident is irresistible. This study aimed to examine those conflict situations. Data were collected using a video recorder placed on the way and an observational grid at the hand of trained observers. Observation procedures included locating, recording and evaluating the speed and distances, sketching the situation and describing the causes of the conflict. Observers also had audio recorders to report on the traffic situation and the causes of the conflicts. Observers recorded basic data on each conflict, such as date, time of day, light conditions, weather, mixed road users, etc. They also recorded all the circumstances that may contribute to understanding the possible reasons for the occurrence of the conflicts. To facilitate measurement, they mapped the distances between places using power poles, billboards, etc. (Uzundu et al., 2019).

Theories of social psychology are sometimes assimilated into empirical study. In this case, the theory of social norms was translated into a design of study that examined how children, accompanied by adults to cross streets, are influenced by a campaign based on the principles of this theory in an Ultra-Orthodox Jewish community in Israel. In each crosswalk, two trained observers stood on the side of the road and collected data: the first observer documented pedestrians' behaviors while the second was responsible for tracking the total number of vehicles passing. When recording the crossing behaviors of pairs of a young child and an accompanying adult/older child, the observers recorded the behavior of the pair as guided by the accompanying adult or older child. In the second study of the experiment, five trained interviewers who were acquainted with the culture administered questionnaires to the children with permission of their parents (Rosenbloom et al., 2009a, 2009b).

Conclusions

This chapter introduced a large scale of studies based on naturalistic observations in various versions—either as uncontrolled observations, through controlled observations taken by human observers or by electronic systems. Finally, combined methods were introduced that show how one method can complement the disadvantage of another method. In the future, it is likely that new gadgets will be recruited for data collecting in real-life observations, so we will gain many insights regarding human behavior on road. This will surely increase safety on roads and prevent fatalities.

Introduction

Learning to drive common motor vehicles or learning to fly small airplanes is, until the very moment of writing, for a large part still a matter of sitting in the chair behind the steering-wheel or the steering-shaft, and start learning by doing it under supervision, in most countries. However, traffic in the air, on the water and on the road is increasingly dense and complex, leading to more victims and costs, while the quickly decreasing acceptance of the underlying accident numbers is approaching a bending within the traffic population. Travelers, and in their footprint politicians, are looking for and demanding drastic measures to enhance traffic safety. The requirements of steering the vehicles safely and efficiently through the air-, water-, and road-ways are increasingly demanding, calling for more adequate, stricter training, and assessment of pilots, helmsmen, and drivers. In a number of countries, this call has led to changes in licensing which in turn stimulated the development of specific simulators. Therefore, simulators are slowly becoming indispensable in most transport areas these days, for obvious reasons, of which safety, cost reduction, and flexibility are the most pregnant ones. Pilot and driver training is much more efficient in simulators, enabling trainers to confront their pupils with a variety of both common and critical situations and events, and everything in between at will.

History and Motivation (Wikipedia was Consulted for the Facts, Figures, and Names)

In 1959, the TX-2 computer was developed at MIT, enabling the integration of man-machine interfaces. From that moment on, a lot happened around computers and graphics. In 1966, the University of Utah recruited David Evans who founded a department around a computer science program, and computer graphics began to flourish under his guidance. His new department became the worldwide famous research center for computer graphics, during more than 10 years, attracting many talented computer scientists. With the general introduction of specialized graphics computers in the 1980s of the last century, the development to take care of the representation and manipulation of (traffic) environment images in 3D started. Based on metal-oxide-semiconductor (MOS) within VLSI (very-large-scale integration) technology, 16-bit central processing unit (CPU) microprocessors and the first graphics processing unit (GPU) chips revolutionized computer graphics, enabling real high-resolution graphics. Then, in the nineties 3D modeling evolved on a mass scale, stimulated by the enhancing quality of computer graphics interface (CGI) generally. This upheaval heralded home computers, enabling to take on the rendering tasks that had thus far been limited to “heavy” graphics computers and workstations such as the famous silicon graphics series, once top of the bill but costing a small fortune. A host of 3D modelers became available for powerful Microsoft Windows and Apple Macintosh machines, enabling university departments, research institutes, and companies to fully exploit the GPU toward the prominence in graphics it still enjoys to date. Driving simulators par excellence profited from this development.

A Small Side Step; The Flight Simulator

Bob Carson developed the *Flight Simulator* in 1977, in fact a series of amateur flight simulator programs for MS-DOS and Mac OS, later followed by versions on Microsoft Windows Operating Systems. It turned out to be the longest-running, best-known, and most comprehensive home flight simulator programs on the market. The flight simulator made you an “airplane pilot” flying all over the world, bringing most of the world’s main airports within reach. No competition for real airplane simulators, of course, but a sign of the time. And, training airplane pilots, being military or civilian, in fact did the same but under strict circumstances, confronting the pilots “in spe” with the earlier mentioned necessary variety of both common and critical situations and events.

Figure 2 Driving simulator mockup and projection (Anno 1996).

Simulation of Motor Vehicles

The first generation of driving simulators, or at least sort of, was primitive, for instance, just a mock-up for basic training to change gears. Before and around the Second World War, trucks were equipped with a rather complex gear changing machinery, the double clutch, which could be trained in a mock-up ([Fig. 1](#)) to avoid damage of the gear box in real trucks.

In the 1970s, several more realistic simulators were developed around the world, some of which were based on television cameras hanging over a running belt mimicking a road, pictures displayed on televisions in front of a steering wheel, and car seat with pedals. The steering wheel would move the camera in lateral directions while gas and brake pedals would control the speed of the running belt. In this way, data could be collected from lateral and longitudinal control of the driver that participated in an experiment, see [Blaauw \(1979\)](#) for an example. This setup would enable studies concerning continuous driving under different conditions, such as research into the effects of sleepiness with time on task. [Blaauw \(1982\)](#) was one of the first to compare driving in a simulator and on the road, in an instrumented vehicle. He came to the conclusion that this type of simulators was well able to produce good absolute and relative validity for longitudinal vehicle control. Lateral vehicle control offered only good relative validity (see also section "Validity").

Driving simulators came to a first level of maturity with the introduction of graphics computers in the eighties. From that moment on, interaction between the driver and the traffic environment could be studied in quickly enhancing graphic surroundings. In a first, simple the traffic environment could be displayed on CRTs at eye height for the "driver," who was sitting on a chair with a steering wheel and pedals in front. Or, more sophisticated, could be projected on screens in front of a mockup to give it a real look and feel ([Fig. 2](#)).

Enhancement of the feeling of driving a real motor vehicle on different types of road came with adding a moving base, enabling 14 degrees tilt all sides ([Fig. 3](#)).

Figure 3 Medium advanced, moving based simulator (Anno 2014).

Applications

The present driving simulators provide an opportunity to evaluate the driving capacity of people that potentially deviate negatively from “normal” driving. For many years now, formal driving capability assessments for a driver license comprised both clinical and on-road driving components, whilst the build-up creates risk issues for the driving evaluator, the public, and the driver. In particular, young drivers, older adults, sick drivers, handicapped drivers, and drivers under influence of psycho-active substances should be able to detect their shortcomings and learn how to compensate or avoid. Simulator evaluations can identify those shortcomings, potentially adding improvement tools to clinical tools, increasing driving capacity (Gibbons et al. 2014). The present on-road evaluation of driving skills cannot match highly standardized driving simulators, that are relatively cheap, cost-effective and time efficient. Gibbons et al. (2014) studied differences of simulator composition with one or three screens and between older and middle-aged drivers. They found a lot of congruence between the simulator conditions, and concluded that a one-screen simulator sufficed for their specific purpose.

Another important research strand for simulator research is the influence of psychoactive substances on driving ability. As early as 1982, O’Hanlon et al. (1982) demonstrated that 10 mg of one of the most popular anxiolytics of the benzodiazepine family, diazepam, affected the driving capacity of professional drivers dangerously. Many people use prescription drugs on a daily basis, which in most cases implies driving motor vehicles. Whereas a host of medicinal drugs is put on the market the past 40 years, testing all of them to disastrous effects on driving capacity has not been done, partly because it is illegal to do that on the road in most countries. Simulators would be the solution. The Center for Addiction and Mental Health (CAMH) in Toronto and McGill University used the Virage Simulation VS500M driving simulator to study and measure the effects of cannabis on driving. Among young recreational cannabis users, a 100-mg dose of cannabis by inhalation had no effect on simple driving-related tasks, but there was significant impairment on complex tasks, especially when these were novel. These effects, along with lower self-perceived driving ability and safety, lasted up to 5 h after use. Veldstra et al. (2012) investigated the effects of 20-mg oral cannabis (Dronabinol) in a driving simulator, and found modest effects on driving performance. But the impairing effects that were observed were negative for traffic safety since they were comparable to driving under the influence of 0.5‰ BAC (legal limit in many countries) or more. Drivers did not seem to be able or prepared to compensate for possible impairing effects. Using simulators enables the exploration of the boundaries of driving safety under influence.

Many vehicle manufacturers operate driving simulators, for example, BMW, Ford, Renault, and FIAT. Many universities also operate simulators, for research. In addition to studying driver training issues, driving simulators allow the manufacturers to study driver behaviour under conditions in which it would be illegal and/or unethical to place drivers. For instance, studies of driver distraction by dashboard gadgets would be dangerous and unethical to do on the road. Brookhuis et al. (2008) investigated the effects of a congestion warning assistant that would warn the drivers in advance of a looming congestion (Fig. 4). The assistant should enable them to either adapt their speed in advance of even taking an alternative route, a facility that is more or less standard in advanced navigation systems these days.

With the increasing use of various in-vehicle information systems (IVIS) among which satellite navigation systems, smartphones, music and e-mail systems, simulators are playing an important role in assessing the safety and utility of such devices. Lately, much of these developments boil down into motor vehicle automation research. Automated driving technology has a great potential to enhance road transportation and improve traffic safety. Automated vehicles are expected to considerably reduce the number of accidents caused by human errors, increase fast and fluent traffic flow, increase comfort by letting the driver engage in alternative tasks and ensure mobility for all people, including older and impaired individuals (Kyriakidis et al., 2017). However, human beings tend to be poor supervisors of automation. With respect to Automated vehicles in particular, up to Level 4 automation, human drivers will be a key component, because they should operate the vehicle in conditions not supported by the automation, and will be expected (Level 4), or even required (Levels 2 and 3), to resume manual control when needed. A number of simulator studies have already demonstrated that the human driver cannot be expected to perceive and compensate for automation failure. Merat et al. (2014) conducted a driving simulator study to investigate drivers’ ability to resume control from a highly automated vehicle when

Figure 4 The congestion warning display as positioned in the simulator.

automation was switched off and manual control had to be resumed. They showed that whether automation transition to manual is based on intervals or on demand, it takes drivers some 35–40 s to resume lateral control of the vehicle in a stable manner. The results of this study indicate that if drivers are out of the loop, due to control of the vehicle in a limited self-driving situation (Level 3 automation), their ability to regain control of the vehicle is better if they are expecting automation to be switched off, that is, staying in the loop. Another problem of Automated vehicles is the perception and reaction of their “fellow” traffic participants in the immediate environment. Forecasting what the Automated vehicle will do might lead to irregular behavior of pedestrians and cyclists. A lot of research is still needed to determine when and where full automation could be allowed and installed, for which simulators are indispensable.

Simulator Validity

Blaauw (1982) was one of the first who compared on-road and simulator driver behaviour. While such comparative studies are not easy to carry out (see also Carsten and Jamson, 2011), they remain the most appropriate means to evaluate and improve driving simulator validity. Most of them relied on behavioral measures to capture the differences between on-road and simulated driving (e.g., Blana and Golias, 2002). More recently, few studies assessed the level of mental workload when driving in a real vehicle or in a simulator and showed contradictory results (e.g., Veldstra, 2014). Blaauw (1982) proposed to assess driving simulator validity based on physical and behavioral criteria. Physical validity corresponds to the extent to which software and hardware components of the simulator reproduce the physical reality of driving. Behavioral validity has been defined as the correspondence between driver behavior in a simulator and on the road. Blaauw (1982) also made a distinction between relative and absolute behavioral validity. Absolute validity is established with the sameness of numerical values in the behavioral measures in the two different environments. Relative validity is concluded when the differences due to the experimental manipulation are of the same order and direction and have a similar or identical magnitude in real and simulated driving conditions (for a discussion, see Veldstra et al., 2015).

Veldstra et al. (2015) and Veldstra (2014) compared simulator and on-road studies into effects of diverse alcohol levels and dronabinol (10 and 20 mg) on driving parameters, among which lateral control over the vehicle. They concluded that the driving simulator proved to be equally sensitive for demonstrating drug-induced effects as on the road driving especially for the road tracking task (Fig. 5). However, since inter individual variability was higher in the simulator than on the road more caution should be taken when testing for equivalence of treatment effects to effects found for alcohol. Nevertheless, the effects of alcohol on lateral control in the simulator indicate a similar, exponential progress on Delta SDLP (Difference between the three BAC levels and placebo), as the exponential effect of comparable alcohol levels on accident risk (Borkenstein, 1964).

Veldstra (2014) investigated the validity of the driving simulator for speed research: comparing speeding in the simulator to speeding in private cars. Fifteen drivers whose driving behaviour was followed in their private cars via so-called black boxes including Global Positioning System (GPS)-technology also drove in the driving simulator. The main parameter was the percentage of speed violations conducted. Road types with speed limits of 30, 50, 80, 100 or 120 km/h were analyzed for speed violations too. The same road types were reiterated in the driving simulator. The results indicated that speed violations committed in the simulator and in the private car depended on road type. Speed violation patterns were similar in relative terms for both settings, but only in the higher speed ranges. Furthermore, the drivers’ perceived physical correspondence between driving in a private car and simulator was related

Figure 5 Delta SDLP (+95% CI), that is, difference to placebo, for three alcohol level conditions (A), the “Borkenstein curve,” relating BAC and relative accident risk (B).

to the extent that speed patterns in both environments were similar. This suggests that the driving simulator is a relatively valid instrument to assess speed violations, predominantly in the higher speed ranges.

Most traffic accidents can be attributed to driver impairment, for example, inattention, workload, fatigue, etc. It is now technically feasible, and tested the limits in simulators, to monitor and diagnose driver behaviour with respect to impairment with the aid of a limited number of (in-vehicle) sensors. A valid framework for the evaluation of driver impairment, and a method to assess absolute and relative criteria was proposed (see [Brookhuis et al., 2003](#)). Criteria for when impairment is below a certain threshold, leading to accidents, have been established in the simulator. Accidents and mental workload (either high or low) were related to each other, in conjunction with the origins of mental workload such as information overload, boredom, fatigue, or factors such as alcohol and drugs. The traffic environment and traffic itself will only gain in complexity, at least in the near future, with the rapid growth in numbers of automobiles and electronic applications. The study of the consequences of this forecast will naturally concentrate in simulators.

Simulator Fidelity

Some studies have paid attention to hardware components of the simulator to improve physical fidelity, but it is relatively well established that behavioral validity is a more important criterion than physical fidelity ([Veldstra et al., 2015](#)). Nevertheless, in driving simulators, the control over, and measurement of driver state is relatively easily derived (although skills are required and it is time consuming). In simulators of certain minimum fidelity, conditions may be created that cannot be matched in the real world, with respect to flexibility, safety and measurement accuracy. The laboratory-equivalence of serious driving simulator environments allows full control with respect to environmental conditions, scenarios and stimuli, and enables physiological measurement of state-related parameters such as heart rate and brain activity. In 2007, The National Advanced Driving Simulator developed by the National Highway Traffic Safety Administration (NHTSA) to conduct human factors research on driver behavior, was the most advanced, high fidelity simulator in the world. The simulator consists of a dome with a vehicle cab inside. The vehicle is attached to a motorized turntable that allows the dome to rotate and simulate different driving conditions. 64 feet of longitudinal and lateral travel and 330 degrees of rotation are used to give motion cues to the driver inside. Different makes and models of car cabs can be utilized. However, soon other institutes in different countries built similar, comparable machines.

The Latest development, according to their developers TNO in the Netherlands, is the Desdemona motion platform, considered unique in the world. It combines a centrifuge design for G-loading with 5 additional degrees-of-freedom. Making it the ideal simulator for motion critical training scenario's. The advanced motion simulation has been investigated for driving under armor in difficult off-road conditions, among others. The motion solutions include one-to-one terrain simulation, and make use of high-fidelity vehicle models.

Simulator Sickness

While driving simulators are a valuable tool for assessing multiple dimensions of driving performance under relatively safe conditions, researchers, and practitioners must be prepared for participants that suffer from simulator sickness. [Brooks et al. \(2010\)](#) describe multiple theories of motion sickness and discuss methods for assessing and reacting to simulator sickness symptoms. Individuals can possibly be identified who are unable to complete a driving simulator study due to simulator sickness with greater than 90% accuracy. Older participants are found to have a greater likelihood of simulator sickness than younger participants. Possible explanations for increased symptoms may be investigated in a simulator, as well as implications for research ethics and simulator sickness prevention.

Simulator sickness is a form of motion sickness (for an overview see, [Johnson, 2005](#)). Motion sickness (MS), more specifically seasickness, has been known and documented since at least the ancient Greeks. Simulator sickness (SS) has been known and

documented since the first helicopter flight simulator was procured in the mid-1950s. The most common signs and symptoms of MS are pallor, cold sweating, nausea, and vomiting. Vomiting is rare in SS. The most common signs and symptoms of SS involve visual symptoms, disorientation, and nausea. Only individuals with intact and normally functioning vestibular systems are susceptible to MS and SS. Several measurement techniques exist. The most practical is the Motion Sickness Assessment Questionnaire (MSAQ, Gianaros et al., 2001). The incidence of SS can range from very low to exceedingly high, depending upon the simulator, tasks, conditions, and population. In most individuals, the symptoms of SS subside in less than 1 h. Residual aftereffects lasting longer than 12 h are relatively rare. Adaptation is the single most effective solution to the problem of MS and SS. Most individuals adapt within a few sessions, some individuals require considerable exposure to adapt, and 3%–5% of individuals never adapt. Susceptibility to SS varies depending upon many factors, including age, flight experience, and prior history of MS. Performance of cognitive, perceptual, and psychomotor tasks is largely unaffected by MS and SS. Motivation to perform, however, is strongly affected.

Conclusion

Simulators are indispensable for training purposes and may be very convenient if not necessary for research, specifically when safety and flexibility are at stake. The time may come that governments demand authorized reports on testing new drugs before marketing and sales to ambulant patients who would regularly drive motor vehicles. Or authorities want to have established that driver support facilities do not dangerously distract drivers. To go after these limits, driving simulators may be given a central role in the near future.

Naturalistic Driving Studies: An Introduction

What is Naturalistic Driving?

Road safety researchers and practitioners need good data to understand factors related to crash risk and many other aspects of driver performance and behavior to improve road safety. These data can come from a range of sources, such as police crash records, roadside observation, experiments on test tracks or driving simulators, and surveys. Each of these can provide meaningful data, depending on the nature of the research question being addressed. A common limitation is their inability to provide an objective measure of behavior across an extended period of time or capture high-risk events as they occur, to shed light on what happens prior to the event, during the event and after the event.

Naturalistic driving studies (NDS) address this gap by enabling prospective, continuous data collection of a range of behaviors on the road in real-world traffic environments. NDS typically involve instrumentation of the vehicle a participant drives routinely in order to observe and document their normal driving behaviors. To date, a number of large scale national and international NDS have been conducted (some of which are described as case studies in this chapter), dozens of smaller studies have been conducted, and many more are planned or underway.

Therefore, it is somewhat surprising that there is no accepted definition of what constitutes NDS or what a study must include to be classified as “naturalistic”. Rather than requiring any specific data collection technologies or methods that NDS should use, researchers have proposed principles or frameworks that NDS should follow. For example, Van Schagen and colleagues suggest that NDS should “provide insight into driver behavior during everyday trips by observing in detail the driver, the vehicle and the surroundings through unobtrusive data gathering equipment and without experimental control” (van Schagen et al., 2011). Lotan and colleagues offer a framework for NDS that spans a range of basic to high-resolution data collection technologies according to the scale of the study (Lotan et al., 2017). Specific technologies are recommended depending on the balance between resolution and scale (Fig. 1).

Typically, an NDS would involve a data collection system that includes a computer that receives and stores continuous data from accelerometers, a global positioning system (GPS), and cameras. Video cameras may capture a driver’s face, the dashboard, areas reachable by the driver’s hands, and the forward and rear roadway. Data collection systems could be custom built, assembled using off-the-shelf components, or use the capabilities of a smartphone, depending on the purpose of the study. While the majority of NDS have been conducted using cars and trucks, NDS have also examined behaviors involving other transportation modes such as motorcycles, bicycles, scooters, and walking.

In order to address the lack of an inclusive definition of a NDS, we offer the following definition: *An NDS is the prospective collection of continuous high-resolution behavioral data in a cohort of road users during uncontrolled driving on public roads without experimental manipulation for a defined period of time, usually for a minimum of a few weeks but could much longer.*

Strengths of NDS

Continuous data collection from multiple sources (e.g., video, GPS, accelerometers, etc.) means that NDS can generate extremely large amounts of data in a relatively short time. Given the richness of the data they supply, naturalistic studies have emerged as an

Figure 1 Framework for Naturalistic Studies. Source: from [Lotan et al. \(2017\)](#).

important tool in the study of road safety. NDS offer a range of behavioral, vehicle and environmental data that can be analyzed repeatedly from a variety of perspectives. NDS are not reliant on the memory of a driver or an observer, or on a specific set of measures or questions. Findings from NDS have informed important research policy debates in the areas of distracted driving ([Klauer et al., 2014](#)), advanced driver assistance systems ([Fitch and Hanowski, 2012](#)), impaired driving ([Dingus et al., 2016](#)), and vulnerable road users ([Ehsani et al., 2020](#); [Li et al., 2017](#)) to name a few.

NDS fill an important role in understanding both existing and emerging behavioral risks, supplementing empirical evidence from crash reports and experimental studies such as simulator research. NDS provide insight into the role of driver behavior in the contexts and conditions in which they drive. They can provide new insights on long-standing problems such as driver fatigue and can contribute to our understanding of contemporary issues such as texting while driving. In the case of distracted driving, police crash reports were used to identify the number and type of crashes that appeared to be related to distraction. Simulator studies were then used to identify how specific distractions could affect certain driving scenarios. Naturalistic studies then informed researchers and policymakers of how distractions translated into actual crash risk. In addition, NDS can provide information about when a distraction was present but no crash occurred and to identify factors that might be protective. Importantly, NDS data tell us not only what is wrong, but provide the necessary evidence to develop mitigations to improve safety.

In order to extract meaningful information from large amounts and various sources of data, novel analytical and statistical methods are being developed to analyze NDS ([Bärgman, 2016](#); [Guo, 2019](#)). While a review of the full range of methods is beyond the scope of this article, one specific approach which is unique to the analysis of NDS video data will be discussed in detail here.

In order to analyze NDS video data, researchers have adapted a widely used method from epidemiology called the case-control study ([Breslow, 1996](#)). In this design, driver behavior in a random sample of routine, uneventful driving segments becomes the *control* sample. The *cases* are made up of driver behavior a few seconds before a crash ([Guo and Hankey, 2009](#)). By comparing driver actions during the cases and controls, the association between certain behaviors and crash risk can be established. For example, several NDS have found that dialing a cell phone while driving is associated with a significantly increased risk of a crash ([Dingus et al., 2016](#); [Klauer et al., 2014](#); [Simons-Morton et al., 2014](#)). In order to reach this conclusion, researchers viewed the control videos and observed how frequently drivers were dialing a hand held cell phone. They also observed how often drivers dialed a cell phone during cases and found that it occurred more frequently just before a crash. Activities that require drivers to take their eyes off of the forward roadway result in the greatest risks.

An important point to keep in mind is that due to their nonexperimental nature, NDS are typically not suitable for conclusions about cause and effect to be definitively drawn ([Carsten et al., 2013](#)). Rather, NDS provide the ability to draw associations which can be observed in the data.

Limits and Considerations of NDS

A key limitation of NDS is the resource intensity of the studies. Instrumentation of vehicles is expensive and complicated. This tends to limit the sample sizes of studies and raises questions about generalizability of the findings. In addition to the resources needed for data collection, an equal or greater allocation of resources is needed to clean, process and analyze the data. This process can be prolonged by issues in data quality or an extended period of “on-boarding” for researchers as they learn how to use and interpret data from multiple, complex datasets.

A further limitation of NDS is that most studies rely on volunteer participants, who are likely to be safer, less risky drivers who are willing to contribute their data for safety research. Combined with the fact that serious crashes are rare events in an individual driver's lifetime, this means crashes occurring in NDS tend to be relatively minor. Some have argued that NDS findings have limited generalizability for safety interventions or policy development because they include crashes that are not representative of serious events that need to be prevented (Knippling, 2015). However, this discounts the value of NDS in advancing an understanding of driving behaviors other than serious crashes. There is currently no other way to observe what drivers usually do when they are driving normally and how often and when they engage in risky behaviors or how they behave in near misses. Furthermore, safety intervention and policy development is rarely reliant on a single source of data. NDS represent one of a constellation of methods and research approaches that can form the basis of effective policy and intervention development.

A common question about NDS is whether the presence of data collection equipment in the vehicle might change participant driving behavior. It seems plausible that the presence of in-vehicle data collection equipment could feel invasive for study participants and may influence their driving behavior, at least initially. The single study on this topic is inconclusive (Ehsani et al., 2017). Qualitative research on the topic found that while some participants quickly forget about the instrumentation, others never become accustomed to its presence, even after an extended period. However, there is no objective evidence that awareness of the instrumentation is associated with crash risk or other risky driving behaviors.

A more subtle, but equally important challenge to the validity of NDS comes from the case-control study design that forms the basis of many key NDS findings related to crash risk. When researchers are reviewing videos of crash events (cases) and routine driving (controls), they are unlikely to be blinded to the outcome of the event. This may result in unequal searching for explanatory behaviors, with a less intense search in the control videos. This “detection bias” is a well-documented issue in clinical case control studies (Haynes et al., 2005; Kopec and Esdaile, 1990) but has not been widely discussed in NDS literature. This limitation of NDS is particularly pronounced when the behavior in question could be subjectively interpreted, for example driving too fast for conditions. Reporting the inter-rater reliability of all human-coded driving behaviors in NDS studies could be an important step in documenting this limitation.

Ethical Issues Related to NDS

NDS studies present distinctive ethical issues related to participant privacy. For example, video data from multiple camera views may capture the behavior of the driver, passengers other road users. Origin and destination information obtained from GPS data could include the place of residence and place of work which may make it possible to identify an individual. In the event of a serious crash, data collected from cameras and accelerometers could provide evidence for who was at fault. For these reasons, rigorous ethics reviews are recommended prior to undertaking NDS studies. Extensive ethics training of all personnel who work with the resulting data is also recommended.

To the extent possible, additional steps to safeguard participants should be taken. For example, most studies analyzing the GPS data will remove the first few kilometres/miles around the origin and destination, reducing the privacy risks. Confidentiality agreements could also be put in place to secure the privacy of the study participants. In the United States, the National Institutes of Health issues a Certificate of Confidentiality which allows data collection with the provision that if these data were ever subpoenaed, they would be considered protected. These Certificates of Confidentiality can be obtained for any study in the United States (National Institutes of Health, 2020). Specific requirements and processes differ from country to country.

Case Studies

In order to provide practical insight for those considering using NDS methods, investigators of several large-scale NDS in Australia, Canada, China, the European Union, and the United States were asked to provide a description of the studies they had conducted according to the list of questions below.

1. Main research question
2. Sample size and inclusion criteria
3. Instrumentation installed
4. Duration of observation per participant
5. High level description of analyses
6. Main findings
7. Lessons learned
8. Funding sources and related issues
9. Other issues

Australia

Main Research Question

The Australian Naturalistic Driving study (ANDS) was launched in 2015 and is Australia's first large scale naturalistic driving study. The objective of the ANDS project was to collect driving data for experienced drivers over 4 months of normal driving. The project was not designed to collect data on crashes, but the data collected will provide insights into how crashes were avoided. The strength of the ANDS dataset is that it contains a longitudinal sample of ordinary driving for experienced Australian drivers and can show us what individual drivers usually do.

Sample Size and Inclusion Criteria

The ANDS sample included 347 vehicles/drivers and 62 secondary drivers. The inclusion criteria were designed to capture normal driving by reasonably to very experienced drivers:

- 21–70 years old, with the aim for an even split between male/female and across 20–35, 36–50, 51–70 year age groups;
- drive a personal vehicle for 4 months and no intention to sell the vehicle during the study period;
- hold an unrestricted driver's licence in the States of New South Wales (NSW) or Victoria (VIC);
- be, or have permission from, the registered owner of the vehicle to participate in the study;
- reside in Sydney, regional NSW, Melbourne, or regional VIC with aim for half in each state and a 70:30 split for metro and regional areas;
- vehicle is sedan, coupe, hatchback, station-wagon or four-wheel-drive/SUV; and,
- drive at least 10 trips per week.

Instrumentation Installed

The Data Acquisition System (DAS) developed by Virginia Tech Transport Institute (VTI) for the SHRP2 project was installed in each vehicle to record driver, vehicle and other road user behaviors in normal and safety-critical situations. Each DAS unit incorporates multiple sensors (e.g., video cameras, a still camera, GPS, radar, accelerometers). A Mobileye system that includes a "smart" forward facing camera and proprietary algorithms was also installed to provide additional automated triggers for potential collisions.

Days/Months/Years of Observation per Participant

Four months of instrumented driving for each participant. Each participant used their own vehicle which ensured they were familiar with the vehicle and were encouraged to drive when, where and as often as they usually do.

High-Level Description of Analyses

Processes were developed that would allow researchers to download and prepare the data in an efficient manner (over 60TB of data resides in a server in the USA) and to house the data on Australian servers for quicker access. Scripts were developed to summaries, visualize, and reduce the large quantity of trips to a more manageable format. This allowed researchers to pinpoint trips of interest depending on the research question and to test the feasibility of possible research questions that the data may be able to answer. These scripts have also been used to identify errors in the data and new scripts have been written to correct or mitigate these deficiencies where possible.

Driver Distraction

Distracted driving is one of the key research areas that has been addressed using ANDS data. Analyses have examined engagement in secondary tasks during everyday driving and the role that various driver characteristics and driving context variables play in influencing the initiation of secondary tasks. These analyses have utilized a small subset of ANDS data (186 randomly selected trips, equating to 2623 min of driving). These trips were manually coded using the four video camera views provided by the DAS. The categorical variables coded for each secondary task event included: secondary task type, passenger presence, driving context, self-regulatory behavior (task interruptions) and any incidents that occurred while the driver was engaged in the secondary task.

The detection and labeling of distraction events as described above were done manually and required watching ANDS videos which is expensive and time-consuming. The use of state-of-the-art machine learning techniques could automate the distraction coding time. Reducing/annotating a random sample of the videos and using it to train a machine learning model to carry out the data reduction for the rest of the dataset is possible. We used pre-trained deep neural networks and random forest to detect driver distraction in the ANDS video data (Elhenawy et al., 2019) (see Fig. 2).

Safety at Intersections

The ANDS data have also been used to analyze how infrastructure designs can affect road user behavior, and in particular speed. Speed data collected during the ANDS were analyzed to identify potential correlations between drivers' free-flow travel speed

Figure 2 Visualization of ANDS data (traffic light state detection—top right quadrant).

through common types of intersections in Australia and the intersection design characteristics as well as to evaluate the associated level of fatal and serious injury crash risk incurred by drivers. The analysis was based on a sample of 93 intersections in Sydney.

Further analysis is looking at the following:

- Speed choice including compliance with speed limit value and speed choice in the context of factors like lane width and traffic calming devices, and situations in which speeding increases crash risk, and by how much.
- Driver headway including changes of time and distance from the vehicle ahead in different driving contexts.
- Interactions with vulnerable road users including investigation of crash and critical incident causation factors; gap and speed choice when passing cyclists; and anticipating pedestrian behaviors at crossings (lane and speed choice; when turning right and left).
- Fatigue including investigation of level of fatigue as a function of distance traveled and time of travel; degree of fatigue versus type of driving (urban versus rural) and analysis of the effects of fatigue on driving performance
- Interactions with intelligent transport systems (ITS) including driver responses to collision warning and crash avoidance technologies.

Main Findings

We have been able to identify and summaries all 192,000 trips recorded during the study, allowing researchers to understand driving habits, including mean trip durations and mean distances. We have also devised methods, including machine learning, to tackle and understand such a large dataset (over 60TB), such as pinpointing particular events of interest, trips and finding and correcting anomalies within the trip data.

Key findings to emerge from the distracted driving analyses are:

- Secondary task engagement is highly prevalent among Australian drivers, with drivers spending approximately 45% of their total driving time engaged in nondriving tasks.
- Older Australian drivers engage in secondary tasks just as frequently as their younger counterparts, but these tasks tend to be shorter and less risky than task engaged in by younger drivers.
- Drivers make strategic decisions regarding when to engage in secondary tasks, such as waiting until the vehicle is stationary; however, they do not appear to consider some contextual factors that may impact risk, such as weather and light conditions.
- Once engaged, drivers interrupt (or temporarily disengage from) only a small percentage (13.5%) of secondary tasks, with 87% of these tasks interrupted to re-engage in the driving task.

Key findings from the use of machine learning to detect and label distraction events.

- The proposed algorithm, when applied to the dashboard camera, achieved 0.609, 0.218, and 0.325 for true positive rate (TPR), the false positive rate (FPR) and the precision respectively. Moreover, for the face camera, it achieved 0.748, 0.344, and 0.651 for the TPR, the FPR and the precision, respectively. These promising results suggest the use of machine learning has potential to automate data reduction tasks from videos from naturalistic studies (Elhenawy et al., 2019).

Key findings from the analysis of travel speeds through common types of intersections in Australia (Mongiardini et al., 2020) include:

- The type of intersection (i.e., roundabout, priority, signalized) is the main design parameter to be found to have a statistically significant influence on driver speed behavior.
- Roundabouts are characterized by average and 85th-percentile travel speeds considerably lower than priority and signalized intersections and they are the only type of common intersection designs that appear to be capable of guaranteeing a low level (<10%) of fatal or serious injury risk.

Lessons Learned

The main lessons from this project are that projects of this nature are expensive and require considerable and continuing financial support. Specific statistical and computing skills are required to manage and query the large and complex datasets of heterogeneous measurements, including geospatial databases. Nevertheless, NDS provide a valuable opportunity for in-depth analysis of how normal drivers interact with their vehicle and the road system which can be used into the future.

Funding Sources and Related Issues

The ANDS is led by TARS Research Centre at UNSW Sydney and involves road safety research centers from three other universities: Monash, Adelaide, and Queensland University of Technology. This consortium obtained government funding totaling around \$3.5 million and \$1 million in-kind, in partnership with road authorities and industry partners.

Other Issues

The dataset is intended to be a resource to answer a multitude of road safety questions; however, there are some caveats on the usage of the data. All partners of the consortium can apply to a governance committee to conduct analyses using the ANDS dataset. Other parties can, in collaboration with members of the consortium, also conduct analyses once permission is obtained from this committee. All researchers must sign and comply with a Data Confidentiality Agreement.

Canada

Main Research Question

The overarching goal for the Canadian Naturalistic Driving Study (CNDS) was to produce a Canadian database for research by a broad range of users with varied capabilities and interests including transportation researchers, academic researchers, government researchers both federal and provincial/territorial, industry and others. The CNDS was conducted using the SHRP2 NDS approach to instrumentation and procedures with the result that the Canadian data can function as an additional data collection site and can be combined or compared with the six US sites on many dimensions. While there are commonalities across all seven sites, there are also a number of important differences with respect to issues such as distracted driving laws.

Some examples of specific research questions were:

- What are the contributing factors to crashes and near-crashes?
 - What are the differences between different roadway characteristics? Urban roads and rural highways?
 - What is the impact of winter conditions?
- What is the prevalence of risky behaviors? Under what conditions do they occur and which drivers are involved?
 - Speeding
 - Drowsiness
 - Impairment
- What can we learn about driver distraction and inattention?
 - What is the incidence of secondary task engagement?
 - Which age groups of drivers are most/least likely to engage?
 - What are the devices and tasks?

- When do they engage?
- How does the behavior of the Canadian drivers compare with that of the US drivers, given the differences in distraction-related legislation?

The ultimate goal is to propose countermeasures based on the findings.

Sample Size and Inclusion Criteria

CNDS data were collected on passenger vehicles and trucks.

Passenger Vehicle Participants

There were 149 passenger vehicle participants made up of teen drivers (aged 18–19), young adult drivers (aged 20–29), middle-aged drivers (aged 30–64), and senior drivers (aged 65 and older). Drivers' own vehicles were instrumented. A total of 150 vehicles were instrumented since a few drivers were replaced. Drivers participated for 24 months, 18 months, or 12 months and data were collected from June 2013 to October 2015 (Klauer et al., 2018).

Truck Participants

There were 25 commercial truck drivers who completed the study. Of the 25 trucks that were instrumented, 5 were driven on long routes (7–10 days on and 3–4 days off) and 2 were double-trailers. Questionnaires and assessments were those used in other commercial vehicle NDS and included driver abstracts and driver logs. Truck data were collected for approximately 12 months. Drivers were recruited through local trucking firms (Sarkar et al., 2018).

The CNDS was based in the city of Saskatoon located in the Canadian province of Saskatchewan. This location had a major advantage for recruitment as the participants were recruited through the province of Saskatchewan Government Insurance (SGI) program. They sent letters to target populations of interest based on desired characteristics (age, gender, postal code, commuter into Saskatoon). Some additional participants were recruited through fliers and media announcements. They were paid \$450 CDN per year for their participation.

Instrumentation Installed

The CNDS used the same DAS that was used in the SHRP2 project with the notable exception of a right over-the-shoulder camera which provided a better view of drivers' hands and their interactions with technology. Truck instrumentation was similar to that in passenger vehicles. The DAS system collected four full-time video streams of forward view, driver view, over the driver shoulder/center stack and right rear view as well as periodic still cabin images that were blurred to preserve passenger anonymity (Fig. 3)

A wide range of vehicle data were collected including accelerometer data, GPS, forward radar, turn signals and vehicle network data, including accelerator, brake pedal activation, ABS, steering wheel angle, seat belt information, airbag deployment, etc. An audio incident recording system enabled the driver to provide a brief account of an event that was useful when reviewing video events later.

At the beginning of the study, drivers completed an extensive battery of assessments and questionnaires addressing functional abilities (perception, cognition, psychomotor, physical), psychological testing (risk taking, sensation seeking), health including medical conditions and medications, sleep factors, safe driving knowledge and driver history.

Days/Months/Years of Observation per Participant

Data were collected for the full duration that drivers drove their vehicles. Passenger vehicle drivers drove their vehicles for 12, 18, or 24 months. Truck drivers drove the fleet trucks for approximately 12 months.

High-Level Description of Analyses

Details of data treatment and reduction procedures:

- Postprocessing of data involved multiple steps involving quality control, filtering over data spikes, detection of spurious data.
- Summaries of driver demographics and driving history; physical and psychological test results.
- Summary measures for trip descriptions: trip length, duration, start time, stop time, minimum and maximum for speed and acceleration.
- Vehicle information such as vehicle age, type and condition, and available technologies.
- For video data: Manual Video coding and annotation; Distraction coding.
- Running event triggers to detect crashes, near crashes, type and severity.
- Produced baseline event records necessary for analyses.
- Several data analysis tools developed to enhance data exploration on the website.
- In addition, several Webinars have been provided for CNDS and SHRP2 data users. They have covered many topics including website use and data analysis methods.

The CNDS INSIGHT website provides a full description of the assessment and testing batteries, vehicle data captured and is available at <https://insight.canada-nds.net/home>. The website provides project background documentation, aggregated and summary graphs and access to the Data Dictionaries to assist users in planning their data analysis approaches. The data and associated documentation for the Canadian Natural Truck Driving Study (CNTDS) are available at <https://insight.canadatruck-nds.net>.

Main Findings

Summary of data for passenger vehicles:

- 83 crashes and 301 near-crashes
- 1,904,813 vehicle kilometers traveled
- 53,718 vehicle hours traveled

Summary of data for trucks:

- 34 crashes, 60 near crashes
- 1,304,000 vehicle kilometers traveled
- 27,500 vehicle hours traveled

Some differences between US and Canadian drivers:

Legislation Differences between Canada and the USA (Han *et al.*, Under Review):

- Secondary task involvement was a contributing behavior to more crashes for US drivers (63.1%) than Canadian drivers (44.7%). However, the Canadian findings were higher than would be expected considering the more stringent Canadian distraction laws.

Distraction & Cell Phone Use (Klauer *et al.*, Under Review):

- Overall, hand-held cell phone use is much lower for Canadian drivers (1.5%) than for US Drivers (5.9%).
- Overall young adult Canadian drivers have much less cell use engagement compared with teen drivers in Canada; whereas in the US, the teen and young adult drivers have similar patterns of cell phone use.
- Canadian teen drivers are the only driver age group that is similar to US drivers in that their cell phone use is similar to US teen drivers.

Crash Types & Contributing Factors (Harbluk et al., 2018):

- The Canadian crashes were most often rear end striking (34%), followed by intersection (22%) and run off road (8%) crashes.
- As might be expected, slippery road conditions contributed to more Canadian than US crashes (23.1% vs US 1.8%).

Lessons Learned

Early on, it became apparent that part of the NDS work would involve educating people on this research approach, where it fits in with other road safety research approaches, and what the many benefits would be not only in the immediate but also longer term. The NDS approach made it possible to ask new types of questions about road safety and to greatly improve the understanding of driver behavior.

Prior NDS work conducted in the 100 Car Study, SHRP2 and the European NDS projects provided a strong basis for the CNDS proposal. Aligning the Canadian project with the SHRP2 and adopting its design, equipment, implementation and data collection and reduction methods was efficient. The benefits continue as the CNDS database is used by researchers since the SHRP2 data provide opportunities for combining and contrasting data in analyses to address research questions.

NDS datasets are large, complex and must be kept secure to protect the integrity of data and the privacy of the participants. There can be considerable costs associated with this. Researchers who use the data must consider in their planning the associated costs and procedures for data access and processing if required.

In addition:

- Cell chip differences were found between those used in the US and those in Canada. The chips in the DAS needed to be replaced and reintegrated.
- Shipping across the border was subject to considerable paperwork & delays.
- Although driving was to take place only in Canada, GPS data clearly indicated that one truck driver did not follow this requirement and drove into the USA.

Funding Sources and Related Issues

The CNDS was conducted under auspices of Council of Deputy Ministers Responsible for Transportation & Highway Safety (<https://comt.ca>) with funding support from the Canadian Federal Government (Transport Canada), the provinces and territories, and the Canadian Council of Motor Transport Administrators (CCMTA).

The success of the project was due to the work and cooperation among:

- Council of Deputy Ministers Responsible for Transportation and Highway Safety
- Transportation Association of Canada (TAC)
- Canadian Council of Motor Transport Administrators (CCMTA)
- Saskatchewan Government Insurance (SGI)
- Saskatchewan Highways
- University of Saskatchewan Psychology Department
- SaskTel
- Transport Canada
- Second Strategic Highway Research Program (SHRP2)
- Transportation Research Board
- Virginia Tech Transportation Institute (VTI)
- Federal Motor Carrier Safety Administration (FMCSA)
- And the many drivers who participated

Other Issues

There are general challenges for NDS projects since they are very large, complex, run over long durations etc. There are specific concerns associated with data collection, use and analysis:

- There are challenges associated with the possibility and ease of data sharing. While there is considerable value in sharing data and conducting analyses across projects, in reality this can be quite difficult for various reasons due to differences in variable definitions, methods of data reduction, etc. The challenges become greater when sharing between countries.
- A general issue when using large data sets such as those from NDS, is for users to have sufficient and appropriate understanding of the data (and their limitations) and knowledge of appropriate analysis methods and how to apply them to the data.
- Working with human data requires researchers to respect and adhere to the policies that are necessary for privacy and security requirements. These requirements are essential to keep our commitment to those who participated in the study, but they may be a new requirement for those not used to working with human data. These requirements are likely to differ from country to country and these requirements are an evolving area within countries themselves.

China

Main Research Question

The overall objective of the study was to evaluate driver behavior, traffic conditions, and traffic safety in Shanghai, China.

Sample Size and Inclusion Criteria

The Shanghai Naturalistic Driving study (SHNDS) was a collaborative research study conducted by the Virginia Tech Transportation Institute (VTTI), the General Motors Company, and Tongji University. The SHNDS was the first large-scale NDS conducted in China using the same data collection system employed in the Second Strategic Highway Research Program (SHRP 2) NDS. The study included five experimental vehicles that collected data over a period of 3 years.

The study included 60 drivers from Shanghai, China. Each SHNDS participant drove one of the five experimental vehicles. To ensure that the data represented regular Shanghai driver behavior, the study excluded professional drivers or taxi drivers and avoided participants from the automobile industry. Other inclusion criteria including owning a vehicle, driving every day, as well as with a reasonable number of years of driving experience.

Instrumentation Installed

The SHNDS instrumented five research vehicles, including two Buick Lacrosses, two Chevy Cruzes, and one Cadillac DTS. The study used the same DAS developed by the VTTI for the SHRP 2 NDS project. The multichannel video configuration was similar to the SHRP 2 NDS, with front, back, driver's hands, and face views. The backup camera was updated to a higher resolution at later stage for better identifying following vehicle manoeuvres. The DAS continuously collected key driving information, including GPS, radar, three-dimensional acceleration, yaw rate, vehicle brake information, etc., from ignition-on to ignition-off.

In addition to driving data from the DAS, the data collection system also recorded information from a commercially available off-the-shelf Mobileye active warning system (AWS). The Shanghai NDS used an A-B design approach with 1 month of the AWS muted (i.e., not showing visual or audio alerts to drivers, but still functioning and recording in the background) followed by 1 month of the AWS active (i.e., showing active visual and audio alert signals to drivers).

Days/Months/Years of Observation per Participant

Each participant drove an experimental vehicle for 2 months. As noted, the AWS was off during the first month and was turned on during the second month. No specific instructions were provided and drivers drove the vehicles as they normally would. Note: due to holidays and other disruptions, the data collection period did vary by participant.

High level description of analyses:

The SHNDS data collected over 5000 h of continuous driving data from 60 drivers. The study identified 14 crashes and 115 near-crashes. Several subsequent projects were conducted, including both proprietary research and research in the public domain.

Main Findings

There are unique characteristics of driver behavior and traffic conditions. For instance, mopeds account for a considerable share of road traffic in Shanghai and a disproportionately large share of severe crashes. Glaser et al. (2017) analyzed the characteristics of moped-car conflicts and identified patterns of on-road vehicle-moped conflict configurations in Shanghai, suggesting that the conflicts could be attributed to the relatively complex traffic environment and risky behavior of moped riders. The study also indicated lower prevalence of hard steering in Shanghai compared to the United States. The Shanghai NDS also been used to evaluate the effects on mobile phone use on drivers' control behavior and lane-change behavior.

Lessons Learned

This multipartner international NDS brings challenges for logistics management and technical support. The unique traffic characteristics and driver behavior associated with the study may require tailored DAS configuration. A thorough evaluation of these characteristics can guide the data collection effort to maximize the research outputs.

Funding Sources and Related Issues

The SHNDS was jointly funded by the General Motors Company, Tongji University, and the National Surface Transportation Safety Center for Excellence at VTTI.

Other Issues

The SHNDS is based on a convenience sample of young-to-middle aged, experienced drivers in a Chinese megacity. The data might not represent the entire driver population and traffic conditions found in China.

European Union

Main Research Question

Stating one main research question in a typical naturalistic driving study is difficult, as the study often aims to provide data for a wide range of research areas. In UDrive, analyses targeted the areas of everyday and risky driving, distraction and inattention, vulnerable road users, and eco-driving. There was one subproject in UDrive per research area, with different researchers (although with some overlap) in each—a typical arrangement for projects funded by the European Commission, as EC calls are typically quite specific about the areas to be addressed. Furthermore, data from cars, trucks and powered two-wheelers (PTWs) were collected in UDrive; each vehicle modality had specific research questions.

Some examples of research questions in UDrive were:

Risky driving

- What environmental factors influence engagement in risky driving behaviors?
- How does traffic culture or country influence engagement in risky behaviors?

Driver distraction and inattention

- Which secondary tasks do truck and car drivers engage in? When, how often and for how long are they performed?
- Do driving task complexity and secondary task complexity influence the decision to engage in secondary tasks?
- Do drivers adapt their safety margins when performing secondary tasks?

Vulnerable road users

- Which factors influence whether car drivers perform a shoulder check before a right turn (UK: left turn) in an urban intersection?
- Which factors influence the lateral distance maintained when a car starts to overtake and passes a cyclist?
- What are the time headways between cars, trucks and powered two-wheelers?

Eco-driving

- When do drivers brake, and is it necessary to brake in each instance?
- Do drivers shift gears in order to avoid high engine speeds and high fuel consumption?

One general research question for the analyses of the car data in UDrive (applicable to many of the specific research questions) was: What are the differences across the five countries where data collection was performed, with respect to (some performance indicator)?

Sample Size and Inclusion Criteria

In UDrive, 287 drivers/riders drove a total of 192 cars, trucks and powered two-wheelers. Data was collected from approximately 230,000 trips with a total duration of more than 50,000 h (2.4 million kilometers). There was one main driver per vehicle, while the remaining participants were secondary drivers who drove the vehicles less.

A total of 120 cars, with 192 main and secondary drivers, were instrumented. The cars were driven in France (30 cars/45 participants), Germany (20/30), the Netherlands (10/33), Poland (30/31), and the United Kingdom (30/53). The participants in France, Germany, Poland, and the UK drove their own cars with the UDrive DASs installed for a duration of one to two years. The participants in the Netherlands drove cars leased by a UDrive partner and provided free of charge. This leasing option was created to increase the number of participants and get data from the Netherlands. All the cars were Renaults (Clio or Megane).

Thirty-two Volvo distribution trucks (48 main and secondary drivers) drove in the Netherlands. The trucks belonged to five different fleet owners and drove on both urban and rural roads (including highways). Finally, 40 Piaggio scooters (47 main and secondary drivers) were driven primarily in a small city in Spain.

Because the project was limited to using only two Renault car models, Volvo trucks and Piaggio scooters, the inclusion criteria were somewhat different across data collection sites (e.g., adherence to criteria were relaxed as there were substantial problems finding drivers of the particular Renault models in Poland and Germany).

Instrumentation Installed

Because there was no suitable off-the-shelf DAS, one was developed as part of UDrive. The installed system had different configurations across the three vehicle modalities, but the same base unit. In its most comprehensive configuration, it collected up to eight video streams simultaneously. The quality, resolution, and sample rate were different for the different cameras—optimized for the specific purpose of the individual video views. For cars and trucks, the DAS collected data from the vehicle's controller area network (CAN) and a MobileEye "smart camera". All vehicles were instrumented with complementary accelerometer, angular rate sensors and GPS.

For cars and trucks, approximately 270 measures were collected, while for the PTWs, there were only around 30 measures, as no CAN-bus or MobileEye data were collected. In addition to the collected data, approximately 50 map attributes were added to the data in postprocessing, and throughout the UDrive analysis an additional 400 measures were created (across all annotations, researchers and analyses). All data were encrypted at the source (in the DAS) and in all data transactions.

Days/Months/Years of Observation per Participant

Most car drivers drove their own instrumented vehicle for 1–2 years. However, drivers in the Netherlands used leased vehicles for approximately 6 months. Most secondary drivers drove substantially less than the primary drivers.

The trucks were mostly shared by the fleet drivers, who typically drove the vehicles for between 1 and 2 years. A subset of the scooter riders had the Piaggios for 1 to 2 years, while the others were used by two sets of drivers (two sequential “waves” of data collection), who rode them for less time.

High-Level Description of Analyses

A substantial part of the analysis in UDrive was dependent on reducing video data to numerical or categorical data through manual annotation. This process varied from annotating entire trips with respect to a range of predefined secondary tasks performed by the drivers to noting down event data, such as weather and road conditions and drivers’ glance behaviors before and during a right turn (left in the UK). In addition to the manual processing, algorithms were developed to automatically extract specific events, such as events in which a car is coming up to a bicyclist on a rural road (using data from the MobilEye system). However, the extraction algorithms were never perfect, so manual confirmation of each event was needed.

Typically, all analysis started with plotting the data, but after that, the researchers in UDrive used a wide range of analysis techniques, ranging from simple descriptive statistics to linear mixed-effect models and machine learning. Details of the analyses can be found in the four UDrive deliverables (Carsten et al., 2017; Dotzauer et al., 2017; Heijne et al., 2017; Jansen et al., 2017).

Note that a tool for managing the data, handling the manual annotations (data-reduction process) and calculating derived measures, events etc., was developed in UDrive. All researchers working with the data used the tool, be it for annotations or writing algorithms in scripts (all in Matlab). The process was such that analysts developed algorithms (e.g., derived measures or filters to extract events) on a small set of the data/trips. Then, approximately weekly, the changes were “pushed”; all scripts were applied to all trips in the database. Statistical analysis and, for example, modeling were then performed on the results (e.g., calculated performance indicators), but independently of the tool processing the data (e.g., using software such as R, Python, Matlab, SAS, or SPSS).

At the end of UDrive we asked all researchers involved in the analysis to estimate what proportion of their UDrive analysis-time was spent on (1) data preparation (excluding manual annotations), (2) interpretation and documentation, and (3) statistics and modeling. The results showed that approximately 75% (SD 10%) of the time was spent on data preparation, while the remaining 25% was split evenly between the other two categories. This is worth keeping in mind when budgeting for naturalistic data projects.

Main Findings

The following describes a selection of the key results:

- There were substantial differences by country in the time drivers used their mobile phones while driving, ranging from almost never (close to 0% of the time in Germany) to approximately 10% (in Poland). Furthermore, the German drivers only performed secondary tasks for 2% of the driving time, while the Polish drivers performed secondary tasks almost 20% of the time.
- Many car drivers overtake bicyclists riding on the roadway with smaller lateral clearance than is recommended, or even legal.
- Car drivers from the Netherlands check their blind spot prior to making a right turn six times more often (27%) than car drivers from France, Poland, or the UK.
- Unexpectedly, car drivers do not keep a shorter time-headway to a powered two-wheeler than to another car.

Lessons Learned

For UDrive, an important limitation was the use of Renault cars exclusively. Including a wider range of vehicle brands would have substantially improved the generalizability of the results. The main reason other brands were not used was lack of access to the CAN-bus data, so having more car manufacturers involved to provide access would have been good. Previous European NDS, such as the EuroFOT project (a Naturalistic Field Operational Test of active safety systems funded by the European Commission that ended in 2012) (Benmimoun et al., 2013), did have more car manufacturers involved in the project, and got more access to CAN-data. However, an issue in EuroFOT was the very limited sharing of data between test sites, making aggregation difficult and reducing statistical power. That is, EuroFOT collected data from more car brands, allowing for more detailed CAN-bus data collection, but the data from each brand was typically collected and analyzed by project partners with which the car manufacturers already had an established collaboration (i.e., “trusted” partners). This compartmentalization prevented in-depth comparisons across countries of, for example, behaviors. However, since the focus of EuroFOT was on system evaluation, this limitation was less of a problem than it would have been for UDrive.

Furthermore, the relatively low number of vehicles and participants per country in UDrive lowered the statistical power of the analyses greatly. Also, even if the number of kilometers driven was high, it was not high enough to include many near-crashes, let alone crashes. If I were to design the study today, I would split it into two: one with everyday driving data with multiple cameras, such as in UDrive; the other study would install smaller, much less expensive event data recorders with video in a much larger set of vehicles (Lotan et al., 2017). The latter study would increase the number of participants for which data is collected (increasing the

statistical power for at least part of the analysis), and capture at least a fair amount of near-crashes. Both studies together would provide a more complete picture of traffic safety than either alone.

Another aspect of data collection is collected data versus analyzable data. In UDrive, most of the collected car data could be (and was) used for analysis. However, for the truck and PTWs, there were significant issues, so an unexpectedly large amount of the data could not be analyzed. In fact, more than half of the collected truck data was unusable (not analyzable). The most common reason was that a positive driver confirmation could not be made: there was no image of the driver, so it was impossible to confirm that the person driving had consented to being part of the study. (Another reason was that even if a positive identification could be made, some camera view(s) were missing). Because the trucks were used by multiple drivers (drivers shared trucks at the company they worked), and not all drivers were part of the study, a “turn-off”-button was added; when it was pressed, nothing was recorded for that trip. However, instead of using the button, drivers damaged the cameras or covered them. We actually had a good on-line monitoring tool for detecting these issues, but because the trucks were not easily reachable (and the actual data collection team was far from “on their toes” in this regard), it could take weeks before the issue was fixed, and then the cameras were damaged again.

For future data collections using fleets, an important pre-requisite would be to make sure that all drivers are on-board with the data collection, and that the data collection team has processes in place for fast repairs. Note that the EuroFOT project also had issues with truck equipment being damaged, reducing the amount of analyzable data.

For the PTWs, the issue was different. Before enrolling in the study, all PTW riders stated how much they expected to ride. Many of the participants substantially overestimated the time they spent riding. Although some drivers had to return the PTW so other riders could be recruited, this issue resulted in a much smaller final dataset than expected for the PTW part of the study. It is recommended that the recruitment strategy and—even more importantly—the participant replacement process be improved to enable quick returns and participant replacements.

In all studies I have been involved in, the DASs have been a bottleneck. The development or integration of the system has taken more time than expected, and piloting the data acquisition has often been cut short due to time constraints. However, there have typically been good reasons for not choosing off-the-shelf solutions. Consequently, I believe that there is a need to allow substantially more time for piloting. Funding agencies must appreciate that need and allow projects to have longer durations.

The tool for annotation and data processing in UDrive was set up in a way that I found problematic. Admittedly, it had the benefit of giving everyone access to all measures, events and annotations, and it had good traceability in terms of demonstrating exactly how each derived measure was calculated from other measures (and/or events), even for chains of derived measures. However, having worked with an alternative (in the EuroFOT project) where data was processed as needed, and scripts, rather than processed data, were shared, I strongly believe in a more decentralized data processing solution. That is, analysts can choose any tool of their choice to interact with the data, and, possibly, when needed, share scripts for specific algorithms and event extractions.

Based on my experience working with NDS data from both Europe and the US over the last 14 years, I strongly recommend making sure that there is some forum or database where quality issues are documented so that they can be easily found and referenced and acknowledge (and promoted) by the organizations handling the data. The documentation must be available to all current and potential users of the data. Typically, smaller experiments and data collections in the domain of traffic safety are performed by very few users, who “know their data”.

However, as NDS data are often used by many researchers in many different organizations over several years, there is a danger that these other users could mistakenly assume that all the data are high-quality. Typical issues include synchronization and sensor bias (see, e.g., Appendix A. Supplementary data in Bärghman et al., 2017), as well as the correctness of the data tracking surrounding road users (e.g., from radar or smart camera data). All three issues can be found in UDrive data—as well as in, for example, SHRP2 data. However, the danger does not lie only in the (possibly poor) quality of the data. If others have created derived measures or extracted events, it is easy to think that they represent a certain thing when they actually represent something different (or may even be incorrect). Without extensive documentation being available, or, even better, talking to the individuals who made the calculations, there is a substantial risk that new users will make incorrect assumptions about the data.

Funding Sources and Related Issues

UDrive won a European Commission grant proposal for €8.0 million in funding for person months. UDrive partners (primarily industry) contributed in kind with an additional €2.7 million. This funding was split among the 19 partners. Additional funding was available for DAS installation, and data acquisition, maintenance and accessibility within the project. However, a main issue (at least so far) for projects funded by the European Commission is that there is no European-level funding mechanism to manage data and keep it available for researchers after the end of the project. As a result, individual organizations have to seek national funding or finance the management and access themselves; as a result, the data are less available to other organizations, valuable knowledge about the details of the dataset can be lost, and—in the worst case—the organizations have to delete costly parts of the dataset or shut down infrastructure.

Other Issues

In a unique approach to data access in the UDrive project, one of the partners (SAFER traffic safety research center) managed all the data (from all data collection sites) and set up a remote access platform. Authorized IP addresses had access to the data and analysis tools, while all processing and calculations were run at SAFER. That is, all involved partners used virtual desktops to do everything

from calculating performance indicators to watching and annotating videos of the drivers (without actually downloading any data). A process for extracting any results (figures, tables etc.) was in place—with the extraction handled centrally.

This remote access platform was the result of substantial discussion and effort that were put into developing the Data Protection Concept (DPC); see [Gellerman et al., 2016](#) for a more detailed overview) (Gellerman, Svanberg and Kotiranta, 2016). The DPC considered data protection, and the associated risks, across the entire data management chain. It also outlined a process that would allow access to research on the UDrive data on equal terms (equal trust in all) for all partners. To gain access, UDrive partners needed to provide a document describing how they handle digital and physical access to the data (through the virtual desktops). This is different from, for example, how US SHRP2 data are accessed: sensitive data (e.g., videos of the participants) can only be accessed by on-site visits to Virginia Tech Transportation Research Institute and a specific site of the Federal Highway Administration (FHWA).

The DPC can be used as a starting point for future (at least European) naturalistic driving studies' data access protocols and processes. However, the General Data Protection Regulation (GDPR) has since become a reality, changing some of the fundamentals of conducting NDS in Europe. For example, deidentification through automated face removal is likely a prerequisite for conducting new large NDS across at least parts of Europe—particularly for the external views (pedestrians, bicyclists etc.). In UDrive we experimented with de-identification, but did not find a good enough tool. When required (depending on the laws of individual countries) we blurred part of the screen instead, but that degraded the usefulness of the data. However, automated driver identification (to verify that the person is among those who provided written consent) would have substantially reduced the efforts needed in pre-processing the data. In UDrive, humans watched still frames from every single trip to make this verification. (Data from other drivers were purged from the database before it was accessible for analysis.) Car license plate de-identification (removal or blurring) is also needed in several European countries. In addition, GDPR increase the requirements for informing each individual driver about each new study done on the data, even if they have signed an informed consent form agreeing to such future research. Given that naturalistic driving data has a very wide range of uses, and is intended to be used for many years, this is a complication that needs to be handled when working with naturalistic driving data.

United States

The primary goal of the SHRP2 Safety research program was to address the role of driver behavior and performance with the goal of improving road safety. To make progress, it is necessary to understand drivers, their vehicles and the driving environment, and most importantly, the interactions of these factors and their impacts on safety. The approach taken was to conduct the SHRP2 naturalistic driving study that was unprecedented in size and scope and will be used to support safety research for many years.

Main Research Questions

The main goal of this study was to collect and compile detailed naturalistic driving data across a large and geographically diverse sample. These data are valuable to transportation safety researchers allowing them to explore how people drive under everyday conditions and also to document the activities or behaviors that precede crashes or near misses, enabling determination of crash risk.

The SHRP2 dataset is useful for research in a broad range of areas including:

- driver behavior and characteristics (e.g., distraction, aggression, speeding, teen drivers, older drivers medical conditions . . .)
- development of driver training programs, education and policy
- improved road design and infrastructure (e.g., road curvature and intersections, rural roads, lighting)
- vehicle systems and development of advanced vehicle safety features
- countermeasure development
- and much more

Sample Size and Inclusion Criteria

More than 3500 drivers participated, ranging in age from 16 to 98. Data collection ran for a 3-year period with most drivers participating for 1 to 2 years. Participants needed to be at least 16 years old, licensed and drive at least 3 days a week. Drivers' own vehicles were instrumented and they received compensation of \$500 USD a year. The sample includes the primary drivers of the vehicles as well as some secondary drivers. The study was conducted at sites in six US states, Florida, Indiana, New York, North Carolina, Pennsylvania, and Washington providing data on a wide range of driving environments.

Instrumentation Installed and Categories of Data Collection

There were three categories of SHRP2 data collection, data on the driver characteristics using a battery of assessments and tests, vehicle sensor data and full time video. Each vehicle was equipped with an onboard DAS which collected continuous data.

Driver Descriptions & Assessments

Demographics & Driving Knowledge	Visual, Perceptual & Cognitive Abilities
Age, Gender, Education etc.	Vision & Cognitive Tests
Driving History Questionnaire	Conner's Continuous Performance Test
Driving Knowledge Survey	Clock Drawing Assessment
Driver's Participation Experience	Physical Strength Tests
Driver Exit Interview	
Psychological Tests	Health Conditions
Barkley's ADHD Screening test	Medical Conditions & Medication
Risk perception Questionnaire	Sleep Habits Questionnaire
Risk Taking Survey	Medical Conditions & Medication at Exit
Sensation Seeking Scale Survey	
Driver Behavior Questionnaire	

Vehicle Data Acquisition:

Multiple Videos	Illuminance sensor
Machine vision eyes forward monitor	Passive alcohol sensor
Machine vision lane tracker	Incident push button
Accelerometer Data (3 axis)	Video
Rate Sensors (3 axis)	Audio (only on incident push button)
GPS	Turn signals
Latitude, Longitude, elevation, time, velocity	Vehicle network data
Forward radar	Accelerator
X and Y position	Brake pedal activation
Xdot and Ydot velocities	ABS
Cell Phone	Gear position
DAS system health checks	Steering wheel angle
Remote upgrades	Speed
	Seat Belt Information
	Airbag deployment
	And many more . . .

Video Data:

The DAS system collected four full-time video streams of forward view, driver view, over the driver shoulder/center stack and right rear view as well as periodic still cabin images that were blurred to preserve passenger anonymity. Full time video enables detailed analyses of driver glance behavior, interactions in the vehicle as well as information about the surrounding driving environment.

High-Level Description of Analyses

After data collection, postprocessing of data involved multiple steps including quality control, filtering over data spikes and detection of spurious data.

The SHRP2 dataset is expected to be useful for researchers for decades. It contains:

- More than 35 million miles of continuous data from over 5.5 million trip files
- More than 1900 light-vehicle crashes, over 6900 near-crashes
- Baseline driving event records necessary for analyses
- More than 1 million hours of video
- Summary data provided on drivers, vehicles, trips & events
- Video coding and annotation, coding for distraction
- Time series information
- Several data analysis tools developed to enhance data exploration
- Data dictionaries
- Information on reduced datasets
- And more . . .

Main Findings

The SHRP2 data have been the data source for many published research projects and continue to be widely used. These projects have provided insights into a wide variety areas including driver behavior, crash risk, the driving environment, infrastructure, weather and technologies. A list with brief descriptions of projects is provided at: <https://docs.google.com/document/d/1GQxjCvz0ZQbCtxekbamLK0uKsEUINmUaSPWJS7t2fBk/edit?usp=sharing>

Lessons Learned

There are several reports published since the completion of SHRP2 data collection that provide useful overviews and discussions. Antin and colleagues provides the methods used to design this large-scale study, recruit participants and presents highlights of the collected data. Their discussion also covers the management of the study and its strengths and weakness (Antin et al., 2019).

A technical report from the project provided several considerations for future projects (Dingus et al., 2014). Human participant protection and ethical review procedures took much longer to complete than anticipated. These tasks were complicated by differing requirements at the multiple study locations. Additional delays arose from procuring and repairing DAS components and from design modifications to the DAS units.

Recruitment procedures required re-evaluation and modification during the participant recruitment process, especially those for specialty populations like young or old drivers. Careful planning but also adaptability and creativity were required to successfully manage a study with such a large number of participants. In NDS studies, data collection and reduction occur over long periods of time. Analyses that are conducted on partial data prior to complete data collection may lead to confusion or misleading results. This can also be disruptive to data management processes.

Funding Sources and Related Issues

The second Strategic Highway Research Program (SHRP2) is a collaborative partnership of the Federal Highway Administration (FHWA), the American Association of State Highway and Transportation Officials (AASHTO), and the Transportation Research Board (TRB).

Other Issues/Additional Information

Information about the SHRP2 data and data access is available at the SHRP2 InSight Data Access Website at <https://insight.shrp2nds.us> (Transportation Research Board of the National Academy of Science, no date). It provides a complete overview of the data set, including updates on new events, new trip summary measures, new enhancement projects, and new documentation as well as data sets that have been developed and are available for use. Links to webinars covering many topics including website use and data analysis methods have been provided for SHRP2 data users.

A citation repository for data sets derived from SHRP 2 NDS is available on the Dataverse at <http://dataverse.vtti.vt.edu/dataverse/shrp2nds>.

The Roadway Information Database (RID) is a companion database to the SHRP2 NDS that provides roadway elements and conditions. These two databases are linked, providing an unprecedented resource to study driver behavior within the context of actual roadway characteristics and driving conditions. More information on the RID is available at <https://ctre.iastate.edu/roadway-information-database-rid/>.

Now that data collection phase has completed, current projects and information can be found on websites supported by implementation partners. The Federal Highway Administration (FHWA; <https://www.fhwa.dot.gov/goshrp2>) and the American Association of State Highway and Transportation Officials (AASHTO; <http://shrp2.transportation.org/Pages/Safety.aspx>) are responsible for implementing the resulting products known as SHRP2 Solutions.

Synthesis of Lessons from across the Case Studies

These case studies represent a cross section of the largest and most sophisticated NDS that have been conducted to date. The issues raised by the authors may not reflect the views of all the investigators and project consortium members involved, but they provide an insight into the logistical and analytical challenges involved in conducting NDS. Some common points across case studies include:

- NDS demand substantial investment, both in terms of data collection and analysis
- Funding agencies may be unfamiliar with this type of research and require education
- Be prepared for problems in the field related to data collection
- If possible, allow for extensive pilot testing of data collection methods
- Allow flexibility in study execution and inclusion criteria once data collection is underway
- Once data collection is complete, data coding and analysis need to be rigorous and consistent
- Recognize there will be a time-lag between the time that data collection is completed and when findings are available

When considering whether to conduct an NDS, researchers may also find it useful to contact those who have been involved in previous studies to address specific questions about their approach

What is the Future of NDS?

NDS are increasingly used to understand human interaction with advanced driver assistance features. NDS methods are also being used to observe how highly automated vehicles interact with other road users and infrastructure. One example is work being conducted by the Queensland University of Technology (QUT) in Australia. They are using NDS during an on-road pilot of

cooperative intelligent transport systems (C-ITS), which will involve a Field Operational Test (FOT) of 6 vehicle-to-infrastructure (V2I) use cases with up to 500 privately-owned vehicles participating (Lewis and Rakotonirainy, 2020).

Canadian (CNDS) data are being used for research supporting advanced driver assistance systems and highly automated vehicle applications (Perez et al., 2016). For example, the Canadian and SHRP2 NDS data have been used to develop naturalistic driving data baselines for highly automated commercial motor vehicles in highway applications (Krum et al., Under Review). SHRP2 NDS data are also being used as experimental stimuli in laboratory based studies (Ehsani et al., 2020).

NDS data collection equipment continues to become increasingly miniaturized, portable or nomadic, and less expensive (Grimberg et al., 2020). These lower-cost data collection methods, such as smartphone applications or Bluetooth-paired devices, can automatically begin data collection when a participant drives a vehicle, can be programmed to record event-triggered video before and after an event, and continuously collect acceleration, braking and GPS data. These data collection approaches allow for larger sample sizes that are not constrained by those who live in close proximity to where vehicle instrumentation can be installed and maintained. They may also allow the participation of drivers who do not own a vehicle or may not receive permission to fit instrumentation into a vehicle (e.g., teenage drivers). Furthermore, it could extend study participation to those who are traditionally under-represented in NDS research such as minorities and those from lower-income households.

Hybrid studies combining data collection methods are also being conducted. In these studies, a small number of participants' vehicles are equipped with high-resolution NDS data collection equipment, while a larger sample use a simplified continuous data collection method, such as the data collection capabilities of smartphone. The findings of these two groups are combined to generate a more generalizable set of findings.

In summary, NDS provide an excellent addition to established research methods in transportation research, offering an unparalleled insight into road user behavior and providing much needed knowledge to improve road safety.

Introduction

The interest in qualitative methods and research has steadily increased since the late 1960s. According to [Bryman \(1997\)](#) it is even older than that, since the Chicago school from the 1920s and 1930s can be seen as an early example of qualitative research. [McLeod \(2019\)](#) pointed out that the use of qualitative methods was a reaction to scientific studies in psychology, such as behaviorism. Behaviorism being more interested in human behavior and actions rather than how humans' constructs meanings and interpret different events.

In research a distinction is made between qualitative and quantitative research because they are based on different methods, which means that they relate differently to the topic of the study.

The goal of quantitative research is to collect as much data as possible, which is then manipulated through various statistical analyses. Data, in this case, can easily be converted into numbers. The goal is to explain the cause and effect (causality), have a sufficiently broad and representative material so that the results can be generalized using a well-defined approach, which can be replicated by other researchers. Qualitative research, on the other hand, is more interested in the research participant's own interpretation of the situation. The ambition is to present the human part of a story ([Jacob and Furgerson, 2012](#)). It recognizes that the social world is complex and dynamic. To achieve this, the researcher has to be actively involved with the participant and be prepared to accept that "multiple realities" exists ([Banister et al., 1994](#)). The goal is not to generalize the findings, instead it is regarded as situational and conditional ([Arksey and Knight, 1999](#)).

Qualitative research takes a phenomenological approach. This means that every understanding of social reality must be based on people's own experience of this reality. The phenomenologist tries to perceive things from the individual's point of view. Although the results can, in some cases, be converted into numbers, this is not the main purpose.

However, quantitative and qualitative research can also benefit from each other. For instance, qualitative research can form the basis for a larger quantitative study. The results can contribute to the design of questionnaires that are then distributed to a larger population. Quantitative studies can contribute with background knowledge prior to the design of qualitative studies and it can help in developing theories.

Compared with quantitative research qualitative studies are more labor intensive, which means that the number of participants in the study, is usually relatively small making it difficult to generalize the results. On a contextual level, qualitative studies can also result in knowledge that is transferable to similar situations, environments, and participants with similar background knowledge (e.g., persons who are novice drivers and their first lessons at a driving school). [Table 1](#) summarizes the differences between quantitative and qualitative research.

Despite the differences between quantitative and qualitative research all science is in some form or another based on sensory experience. The assumption is sometimes that quantitative research methods are objective, versus qualitative ones are subjective. From a positivistic stance, getting access to subjective accounts cannot be done in an objective way ([Kesseba et al., 2018](#)). However, regardless of the method used the researcher(s) need to decide on the topic, how to measure it, analyze it and then how to interpret the results.

All events in life which we observe would be completely meaningless if the brain did not also help to interpret what is happening. If we observe a man running across a street and if we see a car at the same time, we assume that the man is running to avoid an

Table 1 General differences between quantitative and qualitative research

<i>Dimensions</i>	<i>Quantitative</i>	<i>Qualitative</i>
1. Aim	Preparation	Explore the participants interpretation of the situation
2. The relationship between researcher and participants	Distanced	Close
3. The researcher's approach	Outsider	Insider
4. The relationship between theory and research	Confirmation and testing	Develops gradually
5. Strategy	Structured	Unstructured and semistructured
6. The results	Establish general laws, and generalizations (nomothetic)	More specific and focus on the individual (idiographic)
7. The image of social reality	Static and somewhat external in relation to the actor	Process-oriented and something that is socially constructed by the actors
8. Information	Hard, reliable	Rich, in-depth

Source: Developed from *Bryman (1997)*.

accident. We have thus linked two different phenomena and assumed that these in some way affect each other. Our own and others' previous experiences and the situation help us in this. The person is on the street, which leads to a different interpretation than if he was on the pavement. We have thus created a meaning with what is happening.

It could therefore be argued, that it is impossible for us to observe something entirely objectively because without interpretation, our data is meaningless. Interpretation is influenced by cultural, political and personal interests, or as *Banister et al. (1994)* stressed:

"Research is always carried out from a particular standpoint, and the pretence to neutrality in many quantitative studies in psychology is disingenuous. It is always worth considering, then the "position of the research", both with reference to the definition of the problem to be studied and with regard to the way the researcher interacts with the material to produce a particular type of sense" (p 13).

As described in *Table 1*, the quantitative approach is described as nomothetic which can be used to develop theories. Although a theory governs quantitative research, to a greater extent than qualitative research, *Collins and Stockton (2018)* would argue that theories influence almost all aspects of research and that this also include qualitative studies. The problem arises when the theory is regarded as facts which cannot be disputed.

Although qualitative research has many things in common it is important to point out that there are different forms of qualitative research. They include; diary accounts, in-depth interviews, documents, focus groups, case study research, ethnography, participant observations, and life history.

In this article, the focus will be on in-depth interviews although we will touch on some other methods.

Interviews

In an interview the information obtained is via communication, either face-to face or via telephone, or other media. It can help in discovering new territory, beliefs, and meanings. Sometimes it can explore matter(s) which are not possible using quantitative means since they are too complex (*Banister et al., 1994*). However, as *Arksey and Knight (1999)* pointed out interviewing is not only one research method but several. The only thing they have in common is the conversation between an interviewer who asks the question and an interviewee who responds. In the following section, both the design and execution of interviews will be discussed.

Preparation

Before conducting an interview, a great deal of preparation is needed. To start with it is important to understand the topic being studied. Although this could lead to preconceptions, which would be regarded as the enemy of qualitative research. But despite this it could be argued that the benefits from understanding the topic are much greater than the costs (*Arksey and Knight, 1999*). It can help in connecting with the person being interviewed but also enable the interviewer to ask appropriate follow-up questions (i.e., probes). A good understanding of the research literature enables the researcher to develop questions which are relevant and if possible, differ from previous research (*Jacob and Furgerson, 2012*).

Interview Protocols

An interview "protocol" can be anything from structured to unstructured. If the interview is structured, it means that the questions are closed and the answers usually short. Anything that deviates from this is considered disruptive.

Example:

Driving in 60 km/h in an urban area makes my driving better adjusted to other drivers

Strongly disagree 1 2 3 4 5 6 7 *Strongly agree*

The example shows that a structured interview is similar to a questionnaire used in quantitative research. The difference is that the interview is carried out by an interviewer rather than by post or email. For this reason, it is possible to replicate the study and determine if the results have an internal consistency over time (i.e., reliability). In order to test its reliability, the study must follow the same order every time it is performed which is only possible if the format is structured. Because there are so many similarities with quantitative methods, one may ask if such a study can really be called a qualitative study? The problem with this approach is that it is guided too much by already established theories and as a consequence important aspect will be missed. Structured answers can also give a distorted picture of reality because many areas cannot be quantified on a scale from e.g. 1–7.

Unlike an interview based on a structured interview guide, the semistructured one is different. The guide includes fewer questions which allows the interviewer to tailor his/her questions to the person interviewed, rather than following a strict code of practice. One important advantage with using a semistructured approach is that the questions can be adopted and adjusted to the person being interviewed. Another important advantage is that the interviewer might discover something he/she had not anticipated.

In a study aimed to explore driver's attitudes and behavior the methodology chosen was semistructured interviews (Forward, 2006). The following questions, which were inspired by the Theory of Planned Behavior (Ajzen, 1991), tried to elicit the participant's views about the behavior outlined in a scenario describing a driving violation:

- What would the consequences be if you commit this offence?
- Can you think about any reason why you might be driving in the way indicated?
- Can you think about why you would refrain from it?
- Do you believe that people important to you would approve or disapprove of this kind of driving?
- How easy is it to avoid carrying out this behavior?
- Is there anything, or anybody, which could make you to lose control over the situation?
- Have you ever been in a similar situation before?
- Will you drive like this in the near future?

At the end of the interview additional questions were asked about their: age, driving skills, driving experience, if their mood affected their driving, their definitions of a "safe driver", accident involvement, and/or other offences.

The results from this study generated some issues which could not have been achieved using a quantitative study. For instance, the immediate response to the question about consequences of the act varied and depended on the perception of the situation. In a serious situation the response was purely affective and immediate whereas in a low risk situation it was more considered.

Unstructured interviews use open questions. The absence of a template means that the interviewer decides the direction. In some cases, the purpose of the study may be very vague. In other cases, the interviewer becomes aware of the purpose much later. During the course of study, one may encounter something unexpected, which means that the question may change direction during the course of an interview. Hence, the formulation of the theory take place at the same time as the information is collected.

How to construct the questions?

- The language must be easy to understand and suitable for the group to be studied
- Avoid questions which might provoke
- Avoid leading questions:
- Avoid assumptions
- Avoid too personal questions
- If the questions are sensitive, ask them in past tense rather than in the present
- Embed the question. For instance, the question of drink driving can be answered more correctly if it is embedded with other questions about drinking
- Finally test the questions in a pilot study

Sample Size

As previously pointed out qualitative studies are more time consuming than quantitative studies and as a consequence the sample has to be smaller. Since the purpose of the study is not to generalize the results, but to explore meanings, the sampling technique can be fairly flexible. For instance, the researcher might interview one person, who in turn nominates others ("snowball sampling").

A number of studies have discussed the appropriate number of people taking part in the study. Mason (2010) analyzed 560 different studies that had used qualitative methods ranging from structured to unstructured. The results showed that the most common sample size was between 20 and 30 interviews (followed by 40, 10–25). Since both semistructured and unstructured interviews are rather time consuming, sometimes more than one hour, conducting 20–30 interviews would be a considerable task. Especially if we also consider that the interviews will be transcribed (see Data Analysis article). A conclusion is that the sample needs to be large enough to be able to elaborate and uncover important issues and many different perspectives but at the same time not too large, so it becomes repetitive.

Since qualitative research are more concerned with meaning rather than generalization and replication [Mason \(2010\)](#) would argue that: “There is a point of diminishing return to qualitative sample—as the study goes on more data does not necessarily led to more information” (p 1). With other words the research has come to a point of saturation where additional interviews will not add anything new ([Kvale and Brinkmann, 2009](#); [Silverman, 2004](#)).

One problem with this is that saturation is many times used as a reason for not including more interviews although very rarely this is proved ([Mason, 2010](#)) “the cut off between adding to emerging findings and not adding, might be considered inevitably arbitrary” (p 16). Despite this, the author argued that saturation should be a guiding principle for qualitative data.

[Charmaz \(2006\)](#) pointed out that the sample size also depends on the aim of the study. A small study might reach saturation quicker than a larger one. For instance, if the study wants to discuss assessment of novice drivers then fewer interviews might be needed than if the aim was to study the experience of driver training, from start to finish. She also pointed out that the experience of the interviewer is important. An experienced interviewer might be able to collect rich and meaningful data with only a fraction of the interviews needed for a less experienced researcher. Hence the skill of the interviewer is important which we will return to later.

Recruitment

The process of recruitment and the information provided to the person being interviewed is very critical. [Potter and Hepburn \(2005\)](#) stressed at least two questions; the first one, who is being recruited and second, what information is provided to the interviewee.

During the process of recruitment, the participant needs to be well informed. What should and should not be included in such information depends many times on standards recommended by the Ethical committee in each country. However, the following information will help the person to decide if they want to take part or not:

- Who you are and who you work for?
- The aim of the study
- Why the project is being carried out?
- Who benefits from the results?
- Why you want this person to be involved?
- What the participation in the study means
- What kind of questions will be asked?
- What will happen to the data collected?
- Are the person's answers confidential?
- How will the data be stored and who will get access to it?
- Who they can contact if they have any questions?

If they agree to participate the date, time, and location needs to be specified. In this case, the interviewer needs to be flexible which sometimes means meeting after office hours.

The Interview

Interviews are conducted by people from various backgrounds and some might be very blasé believing that it is very easy and common sense ([Arksey and Knight, 1999](#)). This is clearly not the case in research since the interviewer need a range of skills in order to conduct a meaningful interview. “Asking questions and getting answers is much harder task than it may seem at first” ([Fontana and Frey, 2000](#), p. 645).

The qualitative interview can be conducted in different ways:

- One interviewer and one interviewee
- More than one interviewer—one silent and one holding the conversation
- More than one participant—for example, husband and wife
- Group of people who know each other
- Focus groups—where the participants do not know each other, have been recruited via for example, advertisement
- Telephone interview or other media
- One by one

Remember that if only one person is being interviewed then two people on, so to speak, the opposite side of the table can be intimidating.

Data can be registered using:

- Notes
- Some form of recording device
- Both notes and recorder

If notes are being used by the same person carrying out the interview, then only brief notes should be taken. The important thing is to maintain eye contact and really listen to what is being said.

The Opening of the Interview

Both the opening and the ending of the interview need to be done in a professional way using a script (Jacob and Furgerson, 2012). When opening the interview, the interviewer needs to emphasize, yet again, how important it is that they take part. Give an approximate time of the interview but at the same time add that they can stop it whenever they want. Stress that their name will not be included in any report. Finally ask if they accept that the interview is being recorded. The introduction should also be used as form of “ice breaker” with the aim to make the interviewee relaxed. Sometimes, it might be good to start with some easy to answer questions about their background etc.

During the Interview

Depending on the structure of the interview the protocol is used in different ways. If it is structured, it should be followed in an orderly sequence. If on the other hand, it is semistructured the order depends very much on the person being interviewed. The important thing is to make the interview, as much as possible, as an “ordinary” conversation.

Arksey and Knight (1999) described an interview as a “jam session” and the interviewer as a “jazz musician”. The interviewer needs to improvise and adjust the question to the situation. This also applies to how the questions are being asked, what words to use and tone. Sometimes it might be necessary to use a language which the interviewee is more familiar with. Using jargon and too many difficult words can make the interviewee feel ill at ease and sometimes even feel inferior to the interviewer. The balance of power is important, and it is worth remembering that the interviewer has more power than the interviewee and therefore efforts have to be made to reduce this imbalance. Although, this power dynamic has been challenged since it would appear to depend on who the interviewer and the interview are (Riley et al., 2003)

As previously discussed, the experience of the interviewer is important and as Charmaz (2006) pointed out the difference between experienced and less experienced interviewers when it came to the interview itself. This is if we by experience mean that they understand the topic discussed in more detail than the less experienced one. Background information would then help in asking subsequent questions and not only take everything at face values. Although understanding the topic is important, it is also crucial that the interviewer understand how this, together with his/her own experiences, interests, etc, can influence the interviewees response and later how the information will be analyzed (see Data Analysis article). To be self-aware helps in preventing taking control over the interview and ending up with answers which fit preconceived ideas.

To overcome this some researchers, suggest that some form of “reflexivity” is helpful. It means that the interviewer examines both themselves and the relationship with the person interviewed. This would be done to ensure that the interviewer during the conversation stays open-minded, curious, and avoid premature interpretations (Alvesson, 2002; Alvesson and Sköldberg, 2000).

However, this should obviously not lead to excess selfreflection at the expense of attending to the person being interviewed (Riley et al., 2003). The aim is to understand what the interviewer themselves brings to the situation.

Another problem, closely related to the above, is social desirability or response bias. This can happen if the interviewee becomes aware of the interviewer’s standpoint which will influence the response. For instance, if the questions is about speeding in traffic the interviewee may adapt and develop his/her answers in a certain direction that he/she expects the interviewee wants to hear or to legitimize his/her own actions. For example, “No, I never drive too fast or” “I only drive too fast on motorways and roads where there are separate lanes for cars and unprotected road users”. Hence, the person tries to want to conceal the fact that they have committed an offence, or at least rationalize it. Social desirability can also happen even if the interviewer is nonjudgmental if the topic discussed is sensitive and not accepted in wider society.

This was also noted in a study on drinking and driving (Forward et al., 2007). The interviewees were very vague about the number of times they had been drinking and driving. Sometimes they firmly stated that it only had happened once. In order to find out if this was true the interviewer gently returned to this question at a later stage. The second time this was discussed it became clear that it was far from the first time and the reason for doing the same has also changed. To achieve this more honest account of their “stories” was only possible after building some trust with the interviewees. Obviously, drinking and driving is a serious offence so a negative reaction from the interviewer would have affected the interview in a negative way.

Hence, the art of interviewing involves being emphatic but at the same time detached. In connection with this the issue of selfdisclosure has been debated. The recommendations are sometimes to share own experiences with the person being interviewed as a way to connect (Arksey and Knight, 1999). In contrast, others have argued that it can be counter-productive since it can be intimidating in Arksey and Knight (1999). It can also distract the interviewer since they are reminded of past events which can shift the focus from the interviewee to the interviewer. It is therefore argued that report can be established by being a good listener, nonjudgmental and with a genuine interest in understanding the person being interviewed.

During an interview it is not unusual that the interviewee deviates from the subject and starts to talk about something else. This needs to be handled with care and the task it to gently bring them back to the subject without embarrassing them. The question should also be if it is a deviation or not, perhaps it is just another way to answer the question.

To summarize:

- Concentrate on the conversation
- Adjust the order of the questions after the conversation not the script

- Add appropriate probes
- Show that you are interested
- Make the interviewer feel at ease
- Be positive about the person you are interviewing. Do not show any negative emotions (impatience, irritation, etc.)
- Accept what they have to say without condemnation.
- Be aware of body language
- Have a good understanding of the subject and a great deal of selfawareness

End the Interview

Always ask the interviewee if they want to add anything over and above what has been discussed. After that tell them that, you are pleased with their contribution and that it was valuable. Let them know what will happen later and if they will be able to see a draft of the report. If that is not the case tell them that they will be able to receive the final report. Sometimes it might be necessary with a shorter second interview if question arises during transcription.

Focus Groups

Most of what is said about individual semistructured interviews also apply to focus groups which is a form of data collection in conversational format with more than one interviewee. The characteristic of focus groups methodology is that it is often stated that groups, rather than individuals within groups, are the main unit of analysis (Kreuger, 1994; Morgan, 1988). Ideally, focus groups give some insights to the “public” discourse on certain issues, which might be different from “private” views expressed in individual interviews. Furthermore, it is stated that the interaction within groups generates a particular type of data and one advantage of focus groups is the dynamic interaction. “Focus groups can be viewed as performances in which the participants jointly produce accounts about proposed topics in a socially organized situation” (Smithson, 2000, p.105). Focus groups have been described as particularly useful in early stages of research as a means for eliciting issues which participants think is relevant or in development processes where for example, search for new knowledge and contradiction can be studied (cf. Smithson, 2000; Wibeck, 2014).

Limitations of focus groups include the tendency for certain types of socially acceptable opinion to emerge, and for certain types of participants to dominate the research process. The problem of a dominant voice can be dealt with by making the focus groups homogenous for example, in terms of experience, age, education, and sex (Smithson, 2000, p. 107). The ideal size is stated between five and eight/ten participants. With larger groups it can be difficult to moderate the discussion, and it might be risk for subgroups talking simultaneous with each other. The moderator should encourage different group members to speak, for example, if there is one quiet participant. But it need not be a problem if some of the participants are more silent than others; silence is a well-known feature of human interaction (Poland and Pederson, 1998). The focus group method is not merely, as is sometimes argued a quick way to pick up relevant themes around a topic, but a social event that includes performances by all concerned. Moderating focus groups is like other forms of interviewing a skill that has to be learnt by education and training.

Finally, with regard to interviews and focus groups, evaluations need to be made on a regular basis, for nothing is ever prefect and we can always improve.

Summary and Conclusion

The use of qualitative methods in transport research has become increasingly popular. The reason for this is that new territory and events can be discovered and explored, which is not always possible using quantitative methods. The focus is on participants own meaning of events rather than collecting data, which can be quantified. Indeed, the social world is complex and dynamic and cannot always be translated into numbers. In this chapter the focus is on interviews which are one important method, amongst others. To conduct interviews careful planning is necessary. It starts with preparations which include a sound understanding of the topic in question. A protocol is then being constructed, which can be anything from structured to unstructured, all depends on the central aim of the study. However, in this article the use of structured interviews is not recommended if the researcher wants to explore something with as open a mind as possible. The sample size is another important topic to consider and in qualitative studies there is no absolute requirement, instead the notion of “saturation” is often used, which means that additional interviews are unlikely to increase the understanding of the topic. The interview itself starts with an opening, which clearly describes the aim of the study and additional practical information. The actual interview follows, which is not something to be blasé about, believing that it is very easy and common sense. Instead it can be described as a “jam session” in which the interviewer needs to improvise and adjust the questions to the situation. The ending of the interview is as important as the introduction, perhaps the interviewee wants to add additional information and know what will happen next. The chapter ends with a short description of focus groups, which is not dissimilar to interviews but with more than one person. One important element which the interviewer, or the moderator, needs to master is the ability to let all the people in the group feel included and also have a voice. Finally, if a qualitative study is conducted with the respect it deserves it can generate valuable information, which can be used by itself, but it can also form the basis for quantitative studies using a larger sample.

Introduction

Human behavior in traffic, such as risky, distracted, or unskilled driving, is the main cause of road traffic crashes, which are among the leading causes of death worldwide. In addition, motorized transport contributes to noise and air pollution and related health problems and is responsible for a significant share of greenhouse gas emissions. While we observe clear declines of emissions in other sectors, emissions from transport are still higher today than in 1990 (EC, 2020).

In the near future, technological solutions alone can neither sufficiently reduce emissions nor road traffic crashes. Actually, technological achievements like higher fuel efficiency or faster travel time often result in rebound effects towards an equally or even less sustainable behavior. Increasing energy efficiency of cars has, for example, been offset with higher shares of larger, more heavy cars, and owning an "eco-car" may increase driving or consumption in other areas as owners feel they have "done their bit" (Sorrell et al., 2020). Automated driving, which is suggested to reduce safety risks, pollution, and congestion, may bring new challenges when people move farther out of cities as they can better utilize travel time (Nielsen and Haustein, 2018). It may not only increase travel demand but also lead to new types of crashes when people engage in distracting activities as a consequence of (too high) trust in the autopilot (Körber et al., 2018). Thus, the highly needed transition to sustainable transport cannot rely on technological solutions alone but requires behavioral change. To achieve this change, we need to consider what we already know about human behavior and how it can be altered.

Theories of Behavior and Behavioral Change

In transport psychology, behavioral change is understood as the adaption of transport behavior as a consequence of changes in psychological factors and processes, which are assumed to determine behavior. Such changes can be triggered by psychological interventions, by changes in the life-course, or in the social and physical environment (e.g., traffic infrastructure, road safety legislation, social norms, and policies).

This section presents the most relevant theories of behavior and behavioral change, as knowledge about the psychological determinants and processes of behavior change delivers important starting points for the design of interventions. Indeed, it has been shown that interventions that are based on a theoretical framework are more effective in changing behavior than non-theory-based interventions (e.g., Webb et al., 2010).

Theories that Explain Transport Behavior as Deliberate Choices

The most often applied theoretical framework in transport research to explain transport behavior is Ajzen's Theory of Planned Behavior (TPB). TPB is an extension of the Theory of Reasoned Action (TRA), which was introduced by Fishbein and Ajzen. Both theories assume that people make reasoned choices aiming at maximizing personal benefits. According to TRA and TPB, a specific behavior (e.g., driving within the speed limit) results from the intention to engage in this behavior. The stronger the intention, the more likely it is that the intention results in the respective behavior. Intention is influenced by attitude toward the behavior, which is the evaluation of the consequences of the behavior (good/bad), and subjective norm, which is the perception of social approval or

support of the behavior. Subjective norm was first only measured by injunctive norm or related beliefs (e.g., “My friends don’t mind if I drive faster than allowed”) but has later been supplemented by descriptive norm, which is the behavior that is observed in others (e.g., “My friends often drive faster than allowed”). Descriptive norm has been found to be more relevant than injunctive norm for both safety-relevant behavior (e.g., Møller and Haustein, 2014) and mode choice (e.g., Eriksson and Forward, 2011) and is thus a relevant addition to TPB.

While TRA only considers behaviors under complete volitional control, TPB can additionally explain behaviors that are under incomplete volitional control. This extension is possible because of the inclusion of an additional factor, called perceived behavioral control (PBC). PBC describes how easy or difficult a person perceives the conduction of a target behavior (e.g., cycle to work). PBC may be completely determined by actual behavioral control (e.g., if a person cannot take the bike because of snow on the cycling path) but in most cases PBC will differ from actual behavioral control as different people perceive the same situations or environments as more or less supportive for the conduction of a behavior. PBC is assumed to be a direct predictor of both intention and behavior. Thus, according to TPB, intention and PBC jointly determine behavior. When applied for explaining mode choice, PBC mostly relates to the perception of the transport infrastructure. Haustein and Hunecke added the construct of perceived mobility necessities (PMN) to better account for perceived requirements and constraints resulting from the personal living situation, like combined demands from family and work, which require a high level of mobility. PMN as well as actual constraints of the living situation have been found to hamper the use of public transportation and to encourage car use, while the effect on cycling depends on the predominant mobility culture (Thorhauge et al., 2020).

TPB has successfully been applied to explain a wide range of transport behaviors, ranging from the use of different transport modes to safety-relevant behaviors like speeding or drunk driving.

What makes the TPB attractive is that it is a parsimonious model while still being open for the inclusion of additional factors. Indeed, a variety of determinants have been added to complement TPB, most importantly habits and personal norm—constructs that will be introduced later in this chapter. In addition, as the standard attitude measures are often reduced to a positive versus negative evaluation of the behavior or to functional aspects like time and money, attitude has been exchanged or complemented by symbolic and affective motives. In case of mode choice, this includes to what extent the use of a specific transport mode is related to fun and passion (excitement), status and prestige, or freedom and autonomy. Some people perceive freedom when driving a car others when cycling; some are proud about their large SUV others about their electric car or bike; in particular symbolic meanings of transport modes do not only differ individually but also based on social and cultural context (e.g., Ashmore et al., 2020) and are related to self-identity (e.g., as a cyclist), a factor that has also been added to TPB.

Personal norm (PN), is the central variable of the Norm Activation Model (NAM) and is defined as the perceived moral obligation to engage in a behavior. NAM was originally developed by Schwartz and Howard to explain altruistic behavior and has later been expanded to pro-environmental behavior, like the use of active transport modes. NAM views pro-environmental behavior as the consequence of the activation of PN. Similar to altruistic behavior (e.g., helping an unknown person in an emergency situation), many pro-environmental actions are associated with behavioral costs, which may prohibit the activation of PN. Whether PN is activated or not, depends on several conditions. First, people must be aware that a specific behavior (e.g., air travel) has negative environmental consequences (climate change), referred to as *awareness of need or problem awareness*. Second, people need to be aware that their behavior contributes to the problem and thus feel responsible for the consequences of their behavior, instead of ascribing responsibility to the industry or the government (= *ascription of responsibility*). Moreover, people will be more likely to perform the behavior when they think that it will help to solve the problem (*outcome efficacy*). Outcome efficacy depends on the expectation that others will also act pro-environmentally—if not, this, similar as denial of consequences and denial of responsibility, can be used to justify one’s own unsustainable behavior. Finally, NAM states that people must perceive the ability to act according to their personal norm (e.g. be able to use other modes or to omit the trip), which is called self-efficacy and can be compared to TPB’s PBC. NAM is less formalized than TPB and has more complex assumptions, leading to a higher variability on how it has been applied and tested.

While TRA and TPB focus on optimizing one’s own benefits, and NAM focusses on acting in accordance with moral norms, Lindenberg and Steg’s Goal-Framing Theory (GFT) integrates NAM’s normative goal and TPB’s gain goal and additionally considers hedonic goals to influence behavior. All three goals are assumed to frame the way people process information and how they act. What goals are predominant depends both on people’s underlying values and situational factors.

An even more parsimonious model to explain behavior is proposed by the Campbell Paradigm, which has been revived by Kaiser in the domain of environmental psychology. In this model, sustainable travel behavior (e.g., cycling to work) is the result of two compensatory effects: an individual’s environmental attitude and the behavioral costs of the behavior. In case of cycling, costs can result from constraints of the transport environment (e.g., unsafe cycling infrastructure, long distance to work), from not aligning with social norms (e.g., in low-cycling countries), or bad weather conditions, for example. As cycling in Denmark or the Netherlands is less socially “costly” (it may even be more stigmatized not to cycle) and is also facilitated by a dense and safe cycling infrastructure, it does not require high environmental attitudes to become a cycling commuter. By contrast, abstaining from air travel has been identified as one of the most difficult environmental behaviors, which can explain the high discrepancy between attitude and behavior, when measured in a conventional way (separating attitude and behavior). With the General Ecological Behavior scale, Kaiser developed an instrument to assess environmental attitude based on the difficulty of self-reported pro-environmental behavior, presuming that attitude is apparent in the behaviors that a person engages in.

From an intervention perspective, the Campbell Paradigm’s assumptions imply that both lowering the behavioral costs of sustainable travel behavior (e.g., by providing a more supportive cycling environment, better public transport, or by increasing the

Table 1 Intervention strategies targeting selected psychological factors

<i>Variables</i>	<i>Intervention strategies</i>
Attitude	Increasing positive beliefs about the desired behavior, decreasing negative beliefs, for example, through trying out a new behavior (e.g., cycling to work, testing an electric vehicle/e-bike) Providing information about the benefits of the behavior (e.g., w.r.t. health, safety, environment, . . .)
Subjective Norm	Social models Communicating descriptive and injunctive norms Correcting misperceptions of social norms Changing legislation (e.g., ban of diesel cars; seat belt law)
PBC	Providing knowledge and skills (e.g., education, training, courses, trials)
Awareness of need	Information, education
Awareness of consequences	Personalized information about environmental/safety effects of own behavior, individual feedback
Ascription of responsibility	Hypocrisy paradigm (inducing cognitive dissonance)
Personal norm	Commitment

Source: Adapted from Klöckner (2015).

costs of alternative modes) and promoting pro-environmental attitudes are both effective strategies to achieve more sustainable travel behavior (Taube et al., 2018).

Table 1 summarizes the main psychological factors of the presented models and shows the related interventions. A change of attitudes and the underlying beliefs can, for example, be achieved by providing people with the opportunity to test the new behavior, for example through access to an electric vehicle (Jensen et al., 2013), or by encouraging people to cycle to work for a test period (Gatersleben and Appleton, 2007). Whether this results in higher PBC as well, depends on actual barriers of the behavior (e.g., driving range of electric vehicles, availability of charging stations, cycling infrastructure), which need to be addressed if one wants the efforts to try a new behavior to result in an overall positive re-evaluation of that behavior.

In the context of aberrant driving behavior, PBC relates to the ease with which people can avoid the violating behavior and has been identified as the most relevant TPB predictor of engaging in drunk driving (Parker et al., 1992). Thus, here it would be relevant to support people in better planning their activities beforehand, so they do not get into a situation, they in the end find difficult to control. Another strategy is to teach practices, which support their actual and perceived feasibility to control their behavior. Yet, it is also relevant to communicate the individual responsibility for risky behavior and the possibility to exert control over it.

In many areas of road safety, an actual increase of skills (e.g., hazard-perception skills) is more relevant than the perception of (improved) skills. With regard to driving skills, an overestimation of own competences and the belief to be able to control all kind of traffic situations are actually potential safety risks, and thus here the aim is to align objective and subjective skills rather than to increase PBC.

To increase subjective norm, the communication of what others, peers, or role models do can be an effective strategy. However, the right communication is crucial, otherwise the effects can be contrary to what is intended (Keizer & Schultz, 2019). Also the change of legislation can result in a change of subjective norm, as has for example been shown for the introduction of seat belt laws that are generally accepted. This requires, however, that people are made aware of the legislation.

To support personal norm, a private or public commitment to engage in a specific behavior (or abstain from another) can be used and has for example shown a supportive effect in an intervention to break car use habits (Matthies et al., 2006). Another behavior change tool addressing moral motivation is the inducement of hypocrisy as introduced by Aronson and colleagues. Here, cognitive dissonance between people's attitudes and their actual behavior is created by first having people to advocate the importance of a specific behavior (e.g., that it is relevant to avoid flying to protect the environment) and afterwards asking them about their own failure in the respective behavior. The wish to reduce cognitive dissonance is expected to cause increased compliance with one's own attitudes and norms. The hypocrisy paradigm has successfully been applied with regard to several pro-environmental behaviors, however, as it requires face-to-face interaction, its use in practice is quite limited.

Theories of Behavior Change

While the action models presented above aim to explain single behavioral decisions, another group of theories describe the *process* of behavior change. The most prominent model is the Transtheoretical Model (TTM), which has been introduced by Prochaska and DiClemente in relation to health-related behavior. Since then, the TTM has been applied in various behavioral contexts, including transport behavior. TTM considers behavioral change a process of five stages: In the *Precontemplation* stage, people have no intention to change their behavior, either as they do not consider it as problematic or have given up. In the *Contemplation* stage people become aware of the need to change their behavior, while they in the *Preparation* stage actually form the intention and plan to take action, that

Table 2 Intervention strategies related to stages of change

<i>Stage of change</i>	<i>Intervention strategies</i>
Precontemplation	Activating social norms Activating personal norms: Enhancing problem awareness; increasing acceptance of personal responsibility Enhancing goal setting and goal commitment
Contemplation	Providing information about the pros and cons of different behavioral alternatives Helping selecting the best alternative Enhancing PBC
Preparation/Action	Supporting behavioral planning (if-then planning) Providing information on how to overcome potential barriers
Maintenance	Providing feedback about successful goal achievement Helping to cope with the temptation to relapse into the old behavior Providing social support (also relevant in other stages)

Source: Adapted from Bamberg (2013) and Bamberg and Schulte (2018).

is they get ready for change. In the *Action* stage people actually change their behavior, while the *Maintenance* stage focusses on stabilizing the new behavior and preventing relapse. Stage progression is not necessarily a linear process and people may be stuck at specific stages or even fall back to earlier stages as a consequence of external or internal barriers. A critique of the TTM is that psychological factors and processes related to stage progression remain rather vague.

To address this weakness, Bamberg developed a new stage model that goes back to the Model of Action Phases (MAP) by Heckhausen and Gollwitzer. The MAP stresses the goal-directed nature of behavior change, and suggests to break the process of change down to four stages, each characterized by one of the following tasks: deliberating, planning, acting, and evaluating. In the Stage model of Self-regulated Behavioral Change (SSBC), Bamberg specifies through which psychological factors and processes people approach from one to the next stage of behavior change by reverting to assumptions of TPB and NAM.

Support for the SSBC comes from a longitudinal study that followed people interested in the purchase of electric vehicles, in which 85% of transitions between the stages occurred along the paths suggested by the stage model (Klößner, 2014). The model also provides concrete suggestions for psychological interventions to trigger stage progression. This has for example been tested in a phone-based social-marketing campaign aiming to reduce car use (Bamberg, 2013). In the study, people received interventions (personal phone call and specific information material) that were adapted for their specific stage of change, resulting in a significant reduction of car use and increased use of public transportation.

The model has also inspired a Danish cycling campaign (Nielsen and Haustein, 2019). Here, more general information about cycling and its health benefits were provided to raise awareness among people who did not intend to increase cycling yet. For people who had the goal to increase cycling, a customized smart-phone app (a “cycling coach”) helped to set a realistic goal, and goal-achievement was supported by feedback, self-monitoring, and social support. Campaign activities of a municipality were positively related to the number of cycling trips, while controlling for possible confounding factors.

Table 2 provides an overview of intervention strategies for each of the four stages of behavior change. A study that reviewed the effectiveness of different behavioral change techniques to promote walking and cycling found that the inclusion of self-monitoring and intention-formation techniques is most promising (Bird et al., 2013). These measures are most likely even more effective, when applied in the matching stage of behavior change.

Habits

While the previous models referred to behavior (or behavior change) as a consequence of a deliberate intention or decision process, behavior differs in the degree to which it is preceded by a deliberate intention. Some behaviors are performed in the same way as always, rather automatic, without thinking about it—here we speak of a habit, a concept that was first introduced by Triandis.

The more frequently a behavior is performed under the same stable circumstances and leads to the desired outcome, the more likely it will be performed again and turns into a habit that is activated automatically by specific situational cues. This process requires less cognitive resources than deliberate behavioral decisions. However, if people have first established a habit, it is more difficult to change the behavior again.

Habits have, for example, been identified as important predictors of car use and have successfully been integrated into TPB. As strong habits lead to less interest in information about alternative behaviors, established intervention techniques often fail. Therefore, substantial changes of the situational conditions under which the behavior takes place have been suggested as a precondition to change habits. This could, for example, be the provision of a free public transport pass, which should ideally be combined with an intervention targeting psychological factors or processes (also referred to as “Downstream-Plus-Context-Change Interventions,” Verplanken and Wood, 2006) to avoid that behavior goes back to normal when the incentive is removed.

Dual-Process and Dual-System Models

Attempts to integrate conscious, deliberate processes that influence behavior (as explained by models like TPB), and automatic or impulsive processes (including habits), are provided by Dual-process or Dual-system models. These approaches suggest that two separate processes or systems determine our behavioral choices. The first one (also referred to as system 1, implicit or impulsive system) works unconscious, fast and automated and may result in irrational outcomes; the other one works conscious and slower, deliberate and more rational. Depending on factors, such as self-control, cognitive load, or mood, the one or other system is supposed to be dominant.

Implicit evaluative associations, also referred to as implicit attitudes, are part of the impulsive system and are suggested to influence explicit attitudes and behaviors. In contrast to explicit attitudes, which can be self-reported, implicit attitudes are not immediately consciously accessible and are according to Greenwald and Banaji's definition "traces of past experience." Different computer-based measures exist to measure implicit attitudes, such as the Implicit Association Test (IAT), or the Go/No-go Association Task (GNAT). In contrast to self-reported attitudes, these measures are not subject to self-report bias, as participants are not aware of what is measured. While the IAT is widely used in different fields of psychology, its validity and reliability has also been questioned.

A measure to change implicit attitudes is the Approach-Avoidance Task (AAT), in which participants respond to pictures by pulling or pushing a joystick. The specific instructions result in that the majority of pictures with the behavior/subject that should be avoided are pushed away (without knowing the purpose of the task), while the majority of pictures with the desired behavior/subject is pulled toward oneself, resulting in a change in implicit attitudes. The measure has been applied successfully to change implicit attitudes and subsequent behavior like alcohol consumption. More recently, the AAT has also been applied to change implicit drunk driving attitudes (Martinussen and Sømnhovd, 2019).

With regard to dual-system models, different ways on how the impulsive and reflective system influence behavior have been proposed. It has been suggested that spontaneous behavior is better predicted by the impulsive system, and deliberate choices are better explained by the reflective system (*dissociation pattern*). However, there is also empirical support for both systems contributing independently to the explanation of the same behavior (*additive pattern*). Finally, it has been suggested that both system interact to influence behavior (*interactive pattern*). A longitudinal study focusing on the question how implicit and explicit attitudes influence intention and behavior of physical activity (Muschalik et al., 2018) could not find a direct effect of implicit attitudes on behavior but a moderating effect, which support the assumed interactive pattern. With regard to future interventions, this would imply that it is effective to target both implicit and explicit attitudes to achieve behavior change.

Behavior Change as a Consequence of Life Course Events

While psychological models mainly focus on behavior change as a consequence of changes of intra-psychic processes, the interdisciplinary Mobility Biographies Approach deals with behavior change as a consequence of key events in the life course. These events make it likely that current mobility behavior is reconsidered and may be subject to change and existing travel habits are disrupted. Müggenburg et al. (2015) provide a theoretical framework for the Mobility Biographies Approach, in which three types of key events are distinguished:

1. Life events, separated into private events (e.g., child birth, children leaving parental home, road traffic crashes) and events related to the professional career (e.g., entering labor market, starting university; changing the workplace, retirement)
2. Adaptations in long-term mobility decisions, which are residential location and long-term modal decisions (e.g., car ownership, licensing, seasonal ticket)
3. Exogenous interventions, which may be targeted (e.g., provision of information, free public transport tickets, shared bikes) or untargeted (e.g., closure of a bridge, new infrastructure)

According to the framework, these events influence each other, are influenced by long-term processes related to ageing or socialization, period and cohort effects, and determine everyday mobility decisions. In case of long-term and everyday mobility decisions, reciprocal influences are assumed.

Among the events that have been examined most often is residential relocation. Scheiner and Holz-Rau, for example, examined its effect on mode choice and found that moving to suburban locations was followed by an increase in car use, while the opposite was the case for moving into the city. A similar study by de Vos et al. (2018) found that travel attitudes often influence the choice of the new location and that both travel attitudes and travel mode choice change after relocation, aligning over time. This stresses the reciprocal relationship between attitude and behavior that is often ignored in empirical tests of psychological models, although the alignment of attitudes and behavior as postulated in Festinger's Theory of Cognitive Dissonance is generally not questioned or even part of theoretical assumptions.

The Mobility Biographies Approach has, for example, been used as a framework to interpret mobility trajectories of car sharing users (Jain et al., 2020). Here, it has been shown that the reconsideration of car ownership is often triggered by key life events or residential relocation, while car sharing mostly facilitated changes in mobility behavior rather than causing them. Life events, such as retirement, children leaving home or child birth, have thus been suggested as optimal occasions for promoting car sharing either as a means to abolish a car or to avoid buying an additional car.

While the Mobility Biographies Approach mainly focusses on mobility and mode choice, also traffic safety, in particular driving behavior, can be influenced by life events, for example the involvement in a road traffic collision. Crash involvement can lead to posttraumatic stress (PTS), which has been found related to hostile-aggressive driving or anxious driving behavior—both with negative consequences for road safety. It can even lead to driving cessation, which is a key event in itself that can have negative consequences for health, well-being, activity involvement and social inclusion. Apart from PTS, more recently, attention has also been placed to positive psychological consequences of traumatic experiences, referred to as post-traumatic growth (PTG). However, the concept of PTG, the relation to PTS and the joint impact on driver behavior change is still subject to investigation.

Whether and to what extent events in the life course change our behavior is related to a variety of demographic, psychological, and geographic factors and is thus difficult to generalize. But as important life events interrupt our daily routines and behavioral patterns, intervention research understands them as opportunities to change undesired automated behaviors in a positive direction.

Segmentation Approaches as a Basis for Behavior Change

While interventions can be informed by a theoretical framework, as has been shown in the previous sections, another approach to design interventions are user segmentations. This approach is motivated by the aim to create more tailored interventions, which are assumed to be more effective than “one-fits-all” approaches.

A classic example of a user segmentation is the differentiation between captive and choice users of a transport mode. However, in the last two decades much more nuanced user segmentations have been suggested. One of the first ones was developed by Mette Jensen and is based on sociological analysis. She distinguished between passionate car drivers, daily life car drivers, leisure time car drivers, cyclists/public transport users of heart, cyclists/public transport users of convenience and cyclists/public transport users of necessity. Subsequent segmentation approaches with focus on mobility behavior, as for example suggested by Anable or Hunecke, were mostly informed by psychological theory, in particular TPB and NAM, and created based on standardized items and cluster analysis. Ideally, the resulting cluster profiles provide valuable information on how to design and promote interventions to achieve shifts from car to pro-environmental transport modes. Several other areas of application exists, for example changing air travel (Davison et al., 2014) or departure time choice (Haustein et al., 2018),

all of them with roots in behavioral theory. Instead of these post hoc approaches, where the resulting segments are not known beforehand, segments can also be defined a priori, for example, when dividing people into stages of change based on Bamberg's SSBC, which can be done by related stage-diagnostic questions.

In a traffic safety context, segmentations more often take personality traits and/or driving style as a basis to define subgroups of road users that require different types of interventions as traits have been found related to safety-relevant behavior, such as speeding or road anger expression. While certain personality traits are also related to environmental attitudes and behaviors, these are (so far) seldom used in the context of segmentations related to mobility behavior.

Besides approaches that have their roots in psychological and sociological theory, geographic segmentations compare users based on the city, district or neighborhood they live in, certain characteristics of these (e.g., density, land use mix) or their combination. As a specific form of a geographic segmentation (influenced by sociology and psychology), one can consider so-called *mobility cultures*. What mobility culture a region belongs to, does not only depend on spatial factors and the transport environment but also on predominant travel patterns, attitudes and norms as well as mobility-related policies and discourses. While mobility cultures are traditionally described qualitatively, *urban mobility cultures* (Klinger et al., 2013) and *European mobility cultures* (Haustein and Nielsen, 2016) have been identified and described based on quantitative data.

Demographic segmentations divide people into age groups or household types or more specific life-stages or life-styles, which combine several demographic factors, which are linked to travel behavior. In a traffic safety context, the subgroup of young male drivers is particular relevant due to a higher engagement in risky driving, and a particular focus is also placed on the growing group of older drivers. Also travel or traffic behavior itself is used to group people—in a mobility context groups of interest could be car commuters with a short trip to work (thus a potential to change mode choice), in traffic safety it could be people engaging in aberrant driving or road anger expression—in these cases the aim would be to identify target groups for specific behavior change interventions.

What kind of segmentation approach is relevant to choose, highly depends on the purpose of the segmentation, and all approaches have specific pros and cons. Demographic and geographic segmentations allow for an easy identification of members, however, knowledge about the segments' specific needs is restricted. Psychographic segmentations provide better starting points for information and communication strategies based on the attitudinal profiles of the segments, but this requires a higher effort with regard to data collection and analysis.

Although based on different kind of factors, different segmentations approaches may result in the identification of similar groups as has been shown in a comparison of different segmentation approaches of older road users. It can also make sense to mix different kind of factors to combine the advantages of several approaches. Table 3 provides an overview of common approaches in transport research and practice and their main purposes.

Table 3 Segmentation approaches in transport

<i>Approach</i>	<i>Grouping variables (examples)</i>	<i>Purpose (examples)</i>
Psychographic segmentations	Personality traits, attitudes, values, norms, perceived barriers, risk perception, sensation seeking, change intention	Social marketing, basis for psychological interventions
Geographic segmentations	Countries, cities, districts, population density, neighborhood characteristics, traffic infrastructure	Monitoring, basis for policy and long-term infrastructural interventions
Demographic segmentations	Age, gender, occupation, household form	Travel demand modelling, destination choice, residential choice
Behavioral segmentations	Mode choice, trip frequency, driving behavior, traffic violations	Monitoring, identification of target groups for training, courses, incentives, travel demand management

Conclusions

Current psychological models—or at least their empirical operationalization in transport research—often assume a directed causal relation from attitude to behavior. However, there is increasing evidence of a reciprocal relationship. This is also supported by the Theory of Cognitive Dissonance, which assumes that people tend to align their attitudes and behaviors to avoid mental discomfort. From an intervention perspective, this implies that it is both relevant to try to change people's attitudes and to provide opportunities to test or practice new behaviors. The latter may lead to a re-evaluation of attitudes and perceived barriers—if the social and physical environment supports that the new behavior results in a positive experience. Thus, a combination of efforts to improve the social and physical environment with tailored psychological interventions seems most promising to achieve a change of behavior that results in increased health, well-being, and environmental protection.

Biography

Sonja Haustein is a Senior Researcher and Psychologist at the Technical University of Denmark. Her research aims at understanding transport related choices and thereby providing the basis for interventions that facilitate green, safe, and inclusive transport. Key research areas include behavioral change, new transport modes and services, active travel, segmentation approaches, and psychological interventions.

Introduction

When observing travel behavior, it is quite common to note that travel patterns repeat themselves day to day, week to week, and at times even month to month if not year to year (Gärling and Axhausen, 2003). A very common interpretation of this phenomenon is that travel behavior is habitual, but is it really habit or rather the repetition of behavior?

From a social psychology perspective, habit is a concept that is often included in models that explain human behavior (Triandis, 1977). A certain behavior will have an occurrence probability that depends on intention and habit under physiological excitement and objective conditions. Intention and habit exist in a balance that implies that an increase in habit leads to a decrease in intention, and vice versa. Intention is generally defined as the probability that is consciously assigned to a certain behavior: positive attitudes toward the behavior, social norms by relevant others, and situational control are determinants of intention strength (Ajzen, 1991). Habit is generally defined as behavior that has become automatic in reaction to certain cues and keys: it is not intentional and that is the reason why habit makes people do what they have always done even when their intentions are to do something else and behave differently (Neal et al., 2006). Habit is strengthened with an increase in the frequency that these cues and keys are given and an intensification in the learnt tendency to repeat past reactions (Wood and Neal, 2007). As habitual behavior accounts for a large proportion of ordinary activities, it is no surprise that it plays a significant role in one of them: travel.

From a travel behavior perspective, habits are considered to be more complex than repeated behavior (Forward, 2014; Lanzini and Khan, 2017; Ouellette and Wood, 1998; Verplanken and Aarts, 1999). A caveat in travel behavior research is that repeated behavior is not necessarily habitual behavior: replicating a behavior might in fact manifest from the intention (e.g., to drive to work) being formed repeatedly. Accordingly, the key difference concerns the amount and/or depth of information that is searched and processed prior to performing the behavior. Habit has been hypothesized theoretically (Gärling and Garvill, 1993) and proved empirically to be the choice to perform a behavior without deliberation (Gärling and Garvill, 1993; Verplanken et al., 1997). Information processing is in fact the key in distinguishing habit from repeated behavior, as the former implies that the choice is script-based with less information being searched and processes, whereas the latter implies that the choice is rational and goal-directed with more information being processed and the same outcome being obtained. However, a relation exists between habit and repeated behavior, as the goal orientation motivates people to replicate their behavior and then repetition supports habit formation. Habit becomes then important in travel behavior, as repeating one type of behavior implies that the choice of behavior is not dependent only on reason (Aarts et al., 1997) and, when the habit occurs once, it reduces the probability of the choice of a different behavior (Verplanken et al., 1997).

Accordingly, consensus exists that habit allows predicting the future travel behavior of people. However, is the frequency of past behavior the best predictor of future behavior? Even though the model of interpersonal behavior measures habit strength as the number of repetitions of a certain behavior (Triandis, 1977), a difference exists between habit and repeated behavior, and hence a difference exists between modeling habit or inertia. While habit reveals itself as inertia, the opposite is not necessarily true as a behavior can be inertial (i.e., repeated many times) but not habitual. However, the literature on travel behavior seems to use the two terms interchangeably, also because it is very complex to disentangle the different components of inertia given that an inertial behavior can become habitual over time. A wealth of applications has been observed, especially within a microeconomic approach modeling choices for travel modes (e.g., Bamberg et al., 2003; Chatterjee, 2011; Cherchi and Manca, 2011; Gardner, 2009; Gärling and Axhausen, 2003; Kaplan et al., 2017), vehicles (Bauer, 2018; Jansson et al., 2009), parking (van der Waerden et al., 2015), routes (Bogers et al., 2005; Kaplan and Prato, 2012), residential locations (Ralph and Brown, 2017), and departure times (Thorhauge et al., 2020). The objective of these applications is often to influence travel choices from unsustainable, and generally inertial if not habitual, solutions to sustainable, and generally more rational and deliberate, ones. While it appears obvious that a change of routine could be driven by an increased awareness of other alternatives (Fujii et al., 2001), the observation of travel behavior shows

that behavior change is quite difficult to observe. However, at least some level of behavior change cannot be avoided if carbon emissions from transport are to be reduced significantly (Anable, 2005; Banister, 2008, 2011), and this is the reason why it is fundamental to understand how to model and measure habit within the current models of travel behavior. Understanding habit is in fact fundamental if the challenge is to break unsustainable and carbon-intensive habits (see, e.g., Gärling and Axhausen, 2003; Matthies et al., 2006; Verplanken and Wood, 2006).

Given these premises, this article looks at the behavioral theories where habit is prevalently incorporated, the measurement methods that capture habit and its strength, and the directions that research into habitual behavior could pursue.

Models of Habit

When studying travel behavior, three major frameworks may be considered (Lanzini and Khan, 2017), namely the ones based on the Theory of Planned Behavior (TPB, Ajzen, 1991), the ones based on the feeling of moral obligation (e.g., Nordlund and Garvill, 2002), and the ones based on habit (e.g., Aarts and Dijksterhuis, 2000). Habit is therefore one of three fundamental research frameworks, and this explains why it has been considered for long time as integral to the process of explaining travel behavior (e.g., Banister, 1978; Verplanken et al., 1994). While some studies confused on the concept of habit (e.g., Friedrichsmeier et al., 2013), most studies concentrated on habit as an extension of the existing theoretical models that deal in particular with travel mode choice and its changes as the focal point of studying sustainable transport choices. The theoretical models used for explaining travel the explanation of travel mode choice mostly include the TPB (Ajzen, 1991), the Norm Activation Model (Schwartz, 1977), and the Value Belief Norm Theory (Stern et al., 1999). This section looks at the applications of these theories for capturing habit in behavioral models.

Models Based on the Theory of Planned Behavior

The most commonly used theory for explaining travel behavior, and in particular travel mode choice, is the TPB in either the original or a modified version. Generally, studies hypothesize the relation between habit and intention, and then verify empirically whether this relation exists and what its strength is. The most prevalent approach complements the TPB with a measurement of habit (e.g., Bamberg and Schmidt, 2003; Verplanken et al., 1998), while an alternative approach extends the theory by adding the measurement of habit (e.g., Donald et al., 2014; Forward, 2014).

Considering the three main behavioral predictors (i.e., attitudes, subjective norms, perceived behavioral control) that form an intention that precedes behavior, it is possible to measure the strength of habits with respect to the three behavioral predictors and reveal whether they are strong, thus making the relation between intention and behavior weak (Verplanken et al., 1998). Alternatively, it is possible to map the influence of past behavior on future behavior by inducing change to context conditions and hence measuring habit as a mediator of this influence (Bamberg et al., 2003), or simply add habit as behavioral predictor and make the prediction of intention and behavior more accurate (Bamberg and Schmidt, 2003).

Extending the model with moral norms, descriptive norms, and environmental commitment allows explaining travel behavior via intention and habit, while showing that unsustainable behavior is often determined by both intention and habit, while sustainable behavior is affected only by intention (Donald et al., 2014). Extending the model with the Trans theoretical Model of Behavior Change further elaborates the concept by having six phases that not only define, but also describe the formation of habit (Forward, 2014): (1) precontemplation, (2) contemplation, (3) preparation, (4) action, (5) maintenance, and (6) termination. This model extends the TPB that focuses only on preparation and action by working on the awareness of alternative behavior (in the contemplation phase) and the continuation of the changed behavior (in the maintenance phase) that are essential to break through strong habits. An essential element of this model is the recognition that, although positive consequences are the results of the behavior change, negative consequences need to be mapped as well if the behavior is to be maintained and become a new habit.

Models Based on the Norm Activation Model

Another commonly used theory for explaining human behavior is the Norm Activation Model (Schwartz, 1977). Generally, studies map travel behavior and in particular mode choice and its change (e.g., Hunecke et al., 2001; Nordlund and Garvill, 2002).

Considering the processes of activation of moral norms and their transformation into action, and having these processes explain altruistic and environmental behavior, three predictors of behavior are considered: awareness of consequences, assignment of responsibility, and personal norms. The extension of the model to habit assumes that the personal norm of sustainable travel behavior would be a strong predictor of travel choices only without the effect of a contradictory habit (Klöckner et al., 2003; Klöckner and Matthies, 2004). A strong habit stops in fact the norm activation process and mediates the effect of personal norms on travel behavior, while starting directly from the context.

An evolution of the model considers whether people do not behave in accordance with norms, triggering therefore protection mechanisms such as the refusing responsibility for their actions or reframing the context in which they act (Matthies et al., 2006). A further evolution of the model considers the effect of socialization, in relation to both peers and household members, on the choice of travel mode through habit (Haustein et al., 2009; Klöckner and Matthies, 2012). Summarizing, extending the Norm Activation Model to the effect of habit can help explain why people are not able to behave according to their moral motivation.

Models Based on the Value Belief Norm Theory

A third commonly used theory to represent behavior is the Value Belief Norm Theory (Stern et al., 1999). The theory is generally the combination of theoretical concepts of pro-environmental behavior that has been used to explain travel behavior and in particular travel mode choices (e.g., Eriksson et al., 2006; Nordlund and Garvill, 2002; Nordlund and Westin, 2013). The theoretical concepts that are combined in the Value Belief Norm Theory are the Theory of Values (Schwartz, 1992), the Norm Activation Theory (Schwartz, 1977) and the New Environmental Paradigm (Stern et al., 1995).

According to this theory, specific travel behavior is originated by a causal chain of variables that include values, beliefs, and personal norms. Personal norms for sustainable travel behavior are activated by beliefs that external conditions threaten individual values, and accordingly people might act to limit this threat. An empirical evaluation of the theory analyses attempts to break the habitual use of nonsustainable travel modes via extensive discussions with an expert with a focus on potential behavioral change and “implementation plans” (Eriksson et al., 2008). The discussions change the perspective of the behavior into becoming more intentional and hence the habit of nonsustainable behavior into becoming weaker, while the relation between this behavior and the personal norm becomes stronger. The hypothesis is that habit can be broken via interventions focused on influencing pro-environmental values and norms for which there is a belief to act in compliance with them to achieve sustainable behavior.

Models Based on Other Theories

Apart from habits, all these theories include attitudes as predictors of behavior. The relation between habit and attitudes can be expected to be similar to the relation between habit and intention, as intention can be viewed as formed by attitudes, subjective norms, and behavioral control (Ajzen, 1991), or by past behavior, attitudes, and subjective norms (Ouellette and Wood, 1998). In the travel behavior context, the assumption is that habits and attitudes interact in the prediction of travel mode choices in the future. If habit is strong, then the relation between attitude and behavior is weak, and vice versa: then, increasing strength of habit implies a predictiveness loss in attitudes (Aarts et al., 1997; Verplanken et al., 1994, 1997).

Another approach is the mapping of motivations and habit as determinants of travel behavior (Gardner, 2009). Habit forms from repeated behavior that result from the strong intention to perform that behavior. If habit is strong, the behavior is not formed any more by motivation, in line with the inversely proportional relation theorized by Triandis (1977). If habit is not considered, then the role of decision processes in travel behavior choices may be overestimated: accordingly, measurement of habit needs to be included when measuring decision-making processes. Considering habit, attitudes, and motivation helps models to become more applicable in practice.

Habit Measurement

From the theoretical approaches presented in the previous section, it is evident that one of the key aspects for the inclusion of habit in the different theories is its measurement. How is habit operationalized by researchers in the context of the theoretical foundations?

The frequency of behavior is an indicator of strength of habit (e.g., Bamberg, 2000; Triandis, 1977), but also past behavior is at times defined as habit (Ouellette and Wood, 1998). Then, the strength of habit was also measured, with strong habits defined as the ones emerging often and in stable contexts, and weak habits defined as the ones reflecting unusual effectiveness or changeable circumstances (Wood et al., 2002, 2005). However, these definitions do not disentangle properly repeated behavior from habit.

Accordingly, an alternative approach was proposed on the basis of the concept of habit as a script. The response-frequency method (Verplanken et al., 1994) presents situations or scripts that occur naturally and ask participants to choose quickly a travel mode. An increased frequency of a certain choice is assumed to indicate a more script-based or habitual behavior under the assumption that a developed habit is general to different situations and is triggered by having to travel from one place to another. As a criticism of the method was the necessary extensive piloting and demanding administration, an alternative measure was created. The self-reported habit index (Verplanken and Orbell, 2003) records answers to 12 items that comment on a certain behavior on a disagree/agree scale. The assumption is that the responses capture the strength of habit by focusing on the history of repeated behavior, the difficulty of behavioral control, the absence of conscious behavior, the effectiveness of the behavior and an identity level.

More recently, habit strength was measured as the product of context stability and past repeated behavior (Wood et al., 2005). One advantage would appear to be that this measure covers both the preconditions of habit formation in a single index, although one disadvantage (common to other measures) is that this measure can be confounded with other effects (e.g., attitudes) with unknown stability over time. Accordingly, context stability seems to be an essential requisite for the prediction of future behavior and the product is a measure of strength.

Most of the theories described previously are investigated within a microeconomic approach and several studies (as mentioned in the introduction) are based on discrete choice analysis of travel behavior in different contexts. The measurement of habit in these studies is generally based on past repeated behavior that is either obtained from travel diaries or investigated with ad hoc surveys. If habit is the repeated performance of behavior, a legitimate question concerns how people arrive to specific behavioral sequences in terms of combinations of purpose, time of day, departure time, travel mode, and route. Possibly, past behavior is used again because it is the easiest and less risky solution to the need to move from one place to another. Accordingly, even though habitual choice is incorporated into transport modeling and planning, the understanding of the line between intention and habit is often blurred.

Models from revealed preference data tend to avoid direct indicators of habit. Potential indicators would be vehicle kilometers travelled and public transport trips in a unit of time for travel mode choice, measures of the activity space of each person for destination choice, and most frequent departure time for departure time choice. Models from stated preference data include more often indicators of repeated behavior. Examples of indicators are from questions about car ownership, car availability, and use of travel modes in the last week or month, and ownership of season ticket for public transport. When models are to be used for forecasting purposes, simulation at the disaggregate level does not imply problems in the short-term where the repeated behavior over time could be employed to measure habit, but could give problems in the long-term where the assumption of context stability would be difficult to justify.

Even though it appears different to measure habit because of the fact that repeated behavior is the most used indicator, even though it is conceptually something else (as extensively discussed in the previous sections), it is essential to better understand habitual choice to answer the question: what does it take to make people choose sustainable travel behavior? The success of travel demand management measures requires the ability of people to incorporate these measures into their habits.

Future Prospects

The obvious consideration about the literature on habitual travel behavior is its highly diversified character (Schwanen et al., 2012): various theoretical frameworks and measurement methods exist, although arguably a lot of research is more pragmatic in that attempts to evaluate whether interventions to change travel behavior produce the desired effect. A positive development from the methodological perspective (e.g., structural equation models, hybrid choice models) has allowed the theories to be used for empirical modeling studies that incorporate habit indicators and hence explain behavior (and habitual behavior) in more depth.

The key learning when reflecting on sustainable transport choices is that breaking habits to allow for behavioral change requires automaticity to be replaced by reasoned action. The equilibrium between habit and intention is then crucial, as the disruption of automatic responses to keys and cues is possible only when the generation of implementation intentions facilitates the emergence of new habits (Bamberg, 2000; Eriksson et al., 2008). Moreover, the recognition of the value-action gaps between intention and actual behavior is also essential, as it is true that understanding the relation between attitudes and habit is fundamental for modeling behavior, but it is also true that the gap is a major challenge for attitude theories. Incorporating habit may mitigate the value-action gaps (Schwanen et al., 2012), but using the frequency of past behavior to measure habit is somewhat tautological and cannot be confirmed empirically, especially in cross-sectional studies.

What can then be done when thinking about behavior change? Two premises must be considered (Schwanen et al., 2012): (1) the realization that habits are even more central to everyday behavior than many "habit psychologists" suggest; (2) the notion that habit itself has to be reconsidered. While we think that human beings respond automatically to certain cues, we need to think that habit is a tendency or a force. Schwanen et al. (2012) suggest that the second premise emerges from traditions in thinking about habit: the first comes from Descartes and Kant, for whom habit is a routine process that threatens reflective thought; the second comes from Aristotle, for whom moral virtue results from habit that is the mechanization of activity. The first perspective is the one that dominates the travel behavior literature presented above, while the second perspective is about stability and change. Accordingly, the literature should investigate the latter by (1) shifting the focus from repeated behavior to habit formation and renewal in order to understand habit breaking, (2) shifting the focus from the mind to the body and the environment in order to consider them to the same extent, and (3) shifting the focus on one instrument (e.g., information provision) while transcending the behavior/technology dualism. Relevantly, this effort should involve not only users of transport systems but extend to the industry, retailers, advertising companies, media, nontransport agencies, and departments, namely all the factors that contribute to the collective sense-making of different mobility forms (Schwanen et al., 2012).

A different approach is then needed because behavior change towards sustainable transport is needed to start the decarbonization of our communities from transport choices. Research might need more creativity to understand how to move towards carbon-free travel behavior by breaking habits that lead a vast amount of the population in cities all around the world to choose to travel by a private car with an internal combustion engine that is propelled by oil. Perhaps different theories and methods might need to be tested empirically with all the aforementioned stakeholders participating: auto-ethnographies, video-diaries, qualitative studies focused on discussions between researchers, and participants (also focusing on diaries and ethnographies), role-play studies engaged with perhaps performance arts (Schwanen et al., 2012). This visionary proposition will need to be accepted by an academy that often resists less traditional methods, with a positivist approach that should provide insights that will help understand the mechanisms and strategies through which travel habits can be transformed into new carbon-free ones.

Driver Behavior and Performance

Car driving can be divided into two separate but interrelated components: driver behavior and driver performance. Driver behavior refers to a driver's personal driving style, that is, a way how a driver chooses to drive. Driving style or behavior includes such behaviors as preferred speed in general and in a situation given, preferred following distance, overtaking frequency, scanning of the mirrors and environment for potential hazards, and the degree of compliance with traffic rules. The driving style's central issue is the driver's level of risk-taking: driving style can be described in terms of the crash risk. Since driving behavior or style consists of driving habits, it becomes established over a period of years and can be modified similarly to any habitual behavior. Driving style does not necessarily improve with driving experience but is rather related to a driver's attitudes and personality (Elander et al., 1993). For example, drivers with hostile attitudes to other drivers and aggressive personality are more likely to have a risky driving style than drivers with positive attitudes toward others and traffic safety and nonaggressive character.

Driving skills, or in other words, a driver's level of performance and driving abilities, include information-processing and motor skills. As any skills, driving skills can be expected to improve with practice and training, that is, with driving experience (Elander et al., 1993). The importance of practice can be seen in the steep decline of crash risk early months of independent driving after getting a full license. In addition to practice, driving skills are influenced by the driver's general cognitive abilities. The role of the driver's general information-processing and motor ability is emphasized when some of those skills have declined either temporarily (e.g., driving while intoxicated) or permanently (e.g., Alzheimer's disease).

Fig. 1 displays how driving skills (i.e., driver performance) and driving style (i.e., driver behavior (Summala, 1988)) interact and finally determine a driver's crash risk. In this model, a crash is an outcome of both an error and a violation. Risky driving style characterized by violations against safe driving practices reduces the safety margin, that is, time or space available for corrective actions (Summala, 1988), while shortcomings in driving skills including both perceptual and vehicle handling skills increase the likelihood of an error. A driver's perceptual-motor skills are influenced by driving experience and general cognitive abilities. On the other hand, the driving style, including the tendency to violate formal and informal traffic rules and to deviate from safe practices, reflects a person's personality characteristics (e.g., sensation seeking, aggressiveness), attitudes (e.g., hostility), and lifestyle (e.g., alcohol use). In this way, risky personality characteristics may increase the likelihood of risky driving and traffic violations, which can lead to acceptance of narrow safety margins and, thus, less time for corrective actions in the case of an error. For example, a person scoring high in sensation and thrill-seeking is more likely to exceed the speed limit habitually.

Driver Behavior Questionnaire

Structure

Driver Behavior Questionnaire (DBQ) (Reason et al., 1990) is one of the most widely used self-report instrument for measuring aberrant driving. Document search by using the search term "Driver Behavior Questionnaire" (in title, abstract, or keywords) yielded 244 hits in Scopus and 1960 hits in Google Scholar (27.07.2020). The DBQ was initially developed by Reason and colleagues to investigate "the possible distinctions between aberrant behaviors" (Reason et al., 1990). The original fifty items were selected to cover five aberrant driving classes, that is, slips, lapses, mistakes, unintended violations, and deliberate violations. Later, Parker et al.

Figure 1 Two pathways to crash: low driving skills and risky driving style.

surveyed over 1600 British drivers and identified a threefold typology of aberrant driving behaviors including (1) “lapses” as “absent-minded behaviors with consequences mainly for the perpetrator, posing no threat to other road users,” (2) “errors” as “typically misjudgments and failures of observation that may be hazardous to others,” and (3) violations as “deliberate contraventions of safe driving practice” (Parker et al., 1995). Thus, an important distinctive feature between errors and violations is that errors are unintentional and violations intentional, but both are potentially risky. This distinction matches the “two pathways to crash”—driver skills and behavior—displayed in Fig. 1. The DBQ measures the failures of driver skills (error) and driving style (violations) separately. The violations were later divided into highway code violations and interpersonally aggressive violations (Lawton et al., 1997).

The last addition to DBQ is the Positive Driver Behaviors Scale (PDBS) (Özkan and Lajunen, 2005). Özkan and Lajunen (2005) aimed at extending the DBQ toward an omnibus scale, including not only aberrant driver behaviors. The positive driver behaviors aim at “taking care of smooth traffic flow or paying attention to other road users” or “politeness” (Özkan and Lajunen, 2005). The Positive Driver Behaviors Scale contains 14 items, which measure politeness and consideration for other road users.

Both the DBQ and the Positive Driver Behaviors Scale are frequency scales with the following instruction:

“For each item, you are asked to indicate HOW OFTEN, if at all, this kind of thing has happened to you. Base your judgments on what you remember of your driving over, say, the past year. Please indicate your judgments by ticking ONE of the boxes in the grid next to each item. The response alternatives are: Never, Hardly ever, Occasionally, Quite often, Frequently, Nearly all the time.”

Reliability and Validity

The DBQ has been translated into many languages, and it has been used in a large number of countries. Since there are different versions of the DBQ available from the Swedish (DBQ-SWE) 104-item scale (Åberg and Rimmö, 1998) to 9-item mini-DBQ (Martinussen et al., 2013), it is difficult to give an overview about the reliability and validity of the scale. It can be said, in general, that the DBQ scales “violations,” “errors,” and “lapses” show acceptable reliability (reliability coefficient > 0.70) in the majority of studies. The Positive Driver Behaviors Scale has been used only in four studies, and the reliability coefficients have ranged from 0.84 to 0.92 (Ersan et al., 2020; Öz et al., 2014; Özkan and Lajunen, 2005; Shen et al., 2018).

The structural (construct) validity of the DBQ has been investigated in many studies because the fit of the original supposed factor structure in a new driver population is an essential step (after translation) when adapting an existing self-report instrument to a new country, culture or language area. The DBQ factor structure has been investigated mostly by using exploratory factor analysis (EFA) but much less frequently with confirmatory factor analysis (CFA) in which the fit of the assumed (original) DBQ factor structure is investigated by calculating its fit to the newly obtained empirical data. In general, we can conclude that the original three-factor structure of the DBQ based on lapses, errors, and violations can be globally replicated with some minor deviations. As with the reliability analyses, it is difficult to draw simple conclusions about the DBQ construct validity, because of the great variety of forms of the DBQ used in different studies. It is also somewhat common that the researchers add their items to the DBQ depending on their interests, which naturally may lead to small deviations from the original factor structure.

Based on their meta-analysis about the DBQ as a predictor of crashes, De Winter and Dodou (2010) concluded that among the various versions of the DBQ, the two-factor solution (errors and violations) is the most replicable of the DBQ structures (De Winter and Dodou, 2010). Mattsson et al. (Mattsson, 2012, 2014; Mattsson et al., 2015) analyzed the DBQ factor structure by using

Exploratory Structural Equation Model (ESEM). While [Mattsson \(2012\)](#) seemed to find support for the four-factor structure of slips, lapses, aggressive violations, and highway code violations, he called for an update of the theoretical structure and the instrument itself based on recent theories of attention and human error ([Mattsson, 2012](#)). While the study by [Mattsson \(2012\)](#) has been criticized for a too-small sample size ([De Winter, 2013](#)), [Martinussen et al.](#) investigated both first- and second-order factor structures of the DBQ by using a sample of 4335 drivers ([Martinussen et al., 2013](#)). The results showed a great fit for the three-factor (violations, errors, lapses) version of the DBQ. It can be concluded that especially the two-factor (errors and violations) and three-factor (errors, violations, lapses) solutions seem to show high construct validity and reliability.

The criterion validity or predictive validity of the DBQ is difficult to assess. Since the DBQ measures aberrant (i.e., relatively infrequent) behavior, it is challenging to design experimental studies for establishing the correlation to real driver behavior. Correlation to driving in a simulator or a short test drive might not capture aberrant behavior. Correlation to other similar driver behavior instruments is also a questionable method for establishing concurrent validity because those instruments used as criteria can be even less reliable and valid than the DBQ. One way to approach the possible predictive validity of the DBQ is the correlation to risky driving outcomes, that is, a driver's involvement in crashes or penalties. In their meta-analysis of studies containing more than 45,000 respondents, [De Winter and Dodou \(2010\)](#) concluded that the DBQ errors and violations are about equally strong predictors of self-reported crashes. The same authors have found recently similar relations between the DBQ violations score correlates with actual (i.e., non-self-reported) crashes in the level of individual drivers ([De Winter et al., 2018](#)) and at the level of countries ([De Winter and Dodou, 2016](#)). The cumulating research evidence indicates that the DBQ error and violations scores are related to drivers' crash risk, which can be accepted as some degree of concurrent validity. However, it should be noted that the DBQ is a self-report of risky behavior, not crash involvement. The only real proof of validity would be a demonstrated relationship to those driving behaviors measured in actual driving, which the DBQ aims at measuring.

Use and Considerations

Researchers interested in measuring aberrant (risky) driver behavior with the DBQ should bear in mind that the DBQ is a self-report instrument in which the respondents have to report how often they have committed certain risky and sometimes illegal behaviors. As with any self-reports and especially with self-reports of unwanted behaviors, several sources of bias might influence the answers. The DBQ "lapses," for example, measure memory failures (forget where you left your car in a car park), "errors" are cognitive failures (nearly hit a cyclist who has come up on your inside), and "violations" include deliberate rule or norm violations (sound your horn to indicate your annoyance to another road user). So, the DBQ asks forgetful drivers to remember the occasions when they forgot something and the reckless drivers to report their transgressions honestly.

According to Chapman's and Underwood's (2000) study about forgetting near-accidents, about 80% of incidents were no longer reported after a delay of up to 2 weeks ([Chapman and Underwood, 2000](#)). In the DBQ, most of the behaviors are near-misses or even less than that, so we can expect that forgetting biases the DBQ answer. In terms of the DBQ violations, we could expect that socially desirable responding biases the answers to socially non-acceptable items such as those measuring aggression or driving under the influence of alcohol. Surprisingly, experimental studies about the effect of socially desirable responding (self-deception or lying) show that the social desirability bias is not a considerable problem in the DBQ responses ([Lajunen and Summala, 2003](#); [Sullman and Taylor, 2010](#)). Still, future users of the DBQ should bear in mind that forgetting and socially desirable responding are potential sources of bias in the DBQ. These biases might interact with sample characteristics, which means that forgetting and socially desirable responding is more pronounced among certain driver groups.

The best way to reduce the bias related to forgetting and socially desirable responding is to use the DBQ always as an anonymous research instrument and not for evaluating individual drivers. The instruction of the original DBQ reads: "No one is perfect. Even the best drivers make errors or commit violations at some time . . ." ([Reason et al., 1990](#)). When using the DBQ in research, it is essential to emphasize that the behaviors listed in the DBQ are not for detecting bad drivers but for studying real driving.

Driving Skill Inventory

Structure

Like the DBQ, the Driver Skill Inventory (DSI) ([Lajunen and Summala, 1995](#)) utilizes the difference between driving skills and driving style ([Fig. 1](#)). The DSI contains two self-report scales: perceptual-motor skills and safety skills. The DSI asks the respondent to evaluate his or her abilities—either perceptual-motor or safety—in terms of strength to her or his other skills. The instruction states that

"There are many differences between drivers, especially in different components of driving. We all have strong and weak components. Please indicate your strong and weak components by ticking ONE of the boxes in the grid next to each item."

The response scale includes response alternatives "Definitely weak," "Weak," "Neither weak nor strong," "Strong," and "Definitely strong." Hence, the two types of skills—perceptual-motor vehicle handling skills and safety skills—are measured in relation to each other ([Lajunen et al., 1998](#)). In some studies, a comparison to "the average driver" is used ([Martinussen et al., 2014](#)). The choice of instruction depends on the aim of the use and drastically changes the functioning of the instrument. Internal criterion ("own strong and weak characteristics") indicates whether the driver sees himself/herself mostly as a skillful driver with high vehicle

handling skills or as a safe driver, who avoids risks. If an “average driver” is used as a reference point, the DSI measures a respondent’s view of other drivers as much as himself/herself as a driver.

When the internal reference point is used, a driver’s skill or safety orientation may be calculated by dividing the safety skill score by the perceptual-motor (vehicle handling) skill score. A score above one means that a person is safety-oriented, and the score below one means that the person sees his or her perceptual-motor skills stronger than his or her safety skills. While the safety skill and perceptual-motor skills scores can be used as separate correlates in analyses, the ratio of these skills might be more useful in some situations.

A Scopus search (“Driver Skill Inventory” in all fields) returned (4 August 2020) 24 hits while Google Scholar search found 311 documents. While the DSI does not have such popularity as the DBQ, the DSI has been used in many countries and translated into several languages.

Reliability and Validity

Unlike with the DBQ with many alternative scales with different factor structures, the DSI studies have almost solely relied on the original two-factor structure containing a perceptual-skill and safety skill scale (Lajunen and Summala, 1995). The factor structure of these factors seems to be rather stable across countries and different driver groups. While most of the factor analytical studies of the DSI have utilized exploratory factor analysis (EFA), Ostapczuk et al. (2017) investigated the validity of two orthogonal DSI factors by using confirmatory factor analysis (CFA) among less experienced ($N = 130$) and experienced German drivers ($N = 1199$) and found the two-factor structure having satisfactory construct validity (Ostapczuk et al., 2017). Özkan et al. (2006) used a different approach and studied the fit of the theoretical structure by using EFA with target rotations and similarity indexes in samples collected in the UK, the Netherlands, Finland, Greece, Iran, and Turkey. Interestingly, the two-factor structures of DSI proved to be highly congruent in “safe” Northern and Western European countries while the safety skills factor found in Greek, Iranian, and Turkish sample was relatively incongruent in spite of high factor similarity found in perceptual-motor skills (Özkan et al., 2006). Recent Chinese studies applying EFA have found (Wu et al., 2020; Zhang et al., 2018, 2019), a three-factor structure the most appropriate. On the other hand, some other Chinese studies have found support to the original two factors (Shi et al., 2018; Xu et al., 2018). One reason for these small deviations might be in the sizes and types of samples: student samples, non-professional drivers and professional drivers might conceptualize safe and skillful driving differently. Small sample sizes, such as in Özkan et al. (2006), are likely to produce less stable results than large representative samples. In sum, the DSI two-factor structure based on perceptual-motor skills and safety skills seems to show high construct validity in different countries.

All studies applying the DSI have reported some type of reliability coefficient for the two DSI factors. In general, the scales have shown satisfactory internal consistency (reliability coefficients being mostly above 0.80 and often over 0.90). In the three-factor solutions, the reliability coefficients of some scales have been less impressive (around 0.70) but acceptable (Wu et al., 2018; Zhang et al., 2019). Since the internal consistency evaluated with the alpha reliability coefficient depends directly on the number of items, the scales in the three-factor solution might show lower internal consistency than the two-factor solution. It should be noted that basically all studies applying the DSI have found the two factors internally consistent.

Validation of the DSI is more complicated than the DBQ, because the DSI measures a driver’s view of his or her perceptual-motor skills or safety skills either by using an internal reference or by comparing to the “average driver.” It is essential to understand that the DSI is not an objective measure of driver skills, but rather an instrument for investigating a driver’s view of his or her skills. This view can be seen dominated by either “vehicle handling” or “safety concern” and may not reflect a driver’s real objectively measured driving skill level. Therefore, any kind of other skill measures (e.g., performance in a test track or rule knowledge) would not serve as a proper criterion for validation. Strictly speaking, it is impossible to say anything about the actual concurrent or predictive validity of the DSI because of the subjective nature of the instrument.

One way to get some idea of DSI’s possible predictive validity is to investigate if the DSI scales are related to crashes and tickets. A general finding is that the safety skills correlate negatively with crashes (Özkan and Lajunen, 2006; Özkan et al., 2006; Warner et al., 2013) and especially penalties or demerit points (Özkan et al., 2006; Wu et al., 2018; Xu et al., 2018). The relationship between high perceptual-motor skill score and crashes is much less reported (Özkan and Lajunen, 2006; Özkan et al., 2006) while the positive relationship between perceptual-motor skills and penalties seem to be more established (Özkan et al., 2006).

The above-described studies are based on self-reports and, therefore, the crash and penalty reports may be biased by socially desirable responding or forgetting. Eensoo et al. (2010) obtained the traffic violations data from the police database and the data on traffic collisions from the national traffic insurance database (Eensoo et al., 2010) and, thus, can be considered free of the problems related to self-reporting. They found out that among other variables, the overestimated driving skills in DSI were the strongest predictor of speed limit exceeding (Eensoo et al., 2010).

Relationships between DSI scales, outcome variables (crashes, penalties), and risky driving are often presented as validation of the DSI. Instead of being a proof of validity, these relationships found in several studies show that a driver’s view of himself or herself either as safety-oriented and rule-following driver or as a technically skillful driver is reflected in risky behavior and, finally, in crashes and penalties.

Use and Considerations

The DSI is a self-report instrument, so we might expect that the responses suffer from the same sources of bias as the other self-report measures. However, it should be noted that the DSI requires the respondent to evaluate the strong and weak components in their

driving. Due to this instruction, the DSI can be expected to be less vulnerable to socially desirable responding. A driver who wants to give an embellished view of himself or herself would very likely exaggerate both perceptual-motor and safety skills, resulting in a low score in safety orientation. Unlike the DBQ, the DSI does not include items, which are inherently harmful or socially undesirable. Therefore, the respondents should not have any reason to embellish their answers or lie. Ostapczuk et al. (2017) studied the relationship between the DSI and socially desirable responding (SDR) measured by the Driver Social Desirability Scale (DSDS) (Lajunen et al., 1997) and concluded that “The DSI seemed to be only marginally contaminated by SDR” (Ostapczuk et al., 2017).

Conclusions

Both DBQ and DSI are widely used scales, which have shown satisfactory reliability and construct validity. The effect of socially desirable responding, that is, impression management or self-deception, seem to be marginal. Both instruments have been demonstrated to correlate with risky driving and crashes.

Driving Styles as a Multidimensional Concept

Continuous efforts to understand human road behavior and prevent risky driving and traffic violations have led to the concept of driving styles. Driving style is defined as the way the driver chooses to drive or habitually drives, including decisions on speed, headway, and level of attentiveness and assertiveness behind the wheel (Elander et al., 1993). This is not the same as driving skill, which reflects performance or the ability to maintain control of the vehicle and respond adaptively to various complex and demanding traffic contexts (Elander et al., 1993). Whereas driving skill is a behavioral component and is expected to improve with practice or training, driving style is a psychological characteristic influenced by the individual's values and needs in general, as well as specific attitudes and beliefs regarding driving. In other words, driving style is a subjective feature, while driving skill is considered more objective and can therefore be observed and assessed externally and/or technically.

Over the years, the concept of driving style has evolved from a unidimensional perception of risky driving as a reflection of drivers' recklessness and dangerous behavior in general, to a broader multidimensional view of driving behaviors as deriving from a variety of motivational factors. Several attempts have been made to assess driving styles, and particularly their negative and potentially harmful aspects, such as stress, errors, violations, and driving anxiety, as well as aggressive, risky, or dangerous driving. The tools developed for this purpose include: Driving Behavior Inventory (DBI, Gulian et al., 1988, 1989); Driving Style Questionnaire (DSQ, French et al., 1993); The Attitudes to Driving Violations (ADVS, West and Hall, 1997); Driver Behavior Questionnaire (DBQ, Reason et al., 1990); Drivers Behavior Questionnaire (Furnham and Saipe, 1993), Driving Vengeance Questionnaire (DVQ, Wiesenthal et al., 2000); and Dula Dangerous Driving Index (DDDI; Dula and Ballard, 2003). All these instruments share the premise that driving styles reflect individual differences and a habitual way of driving, and thus are fairly stable (Sagberg et al., 2015).

In contrast, the *Multidimensional Driving Style Inventory* (MDSI), first published by Taubman – Ben-Ari, Mikulincer, and Gillath in 2004, is based on the assumption that driving styles may be more comprehensive, including positive as well as negative characteristics of the driver, and may stem from both conscious and unconscious factors that come together to determine how a person drives. The MDSI was designed to conceptualize an individual's habitual driving style as a driving-specific behavior that can explain the extent of involvement in car crashes and traffic violations, both directly and in combination with more general sociodemographic and personality characteristics (Taubman – Ben-Ari et al., 2004). Since its publication, the MDSI has been used in studies around the world, in addition to Israel, where the instrument was originally developed (see Table (Appendix 1) for examples of published international uses of the inventory).

The Multidimensional Driving Style Inventory: Theoretical Principles and Conceptualization

Three principles underlie construction of the MDSI. One, that the complex and multidimensional nature of the phenomenon of driving is best reflected through driving styles. Two, that existing definitions and scales of driving styles need to be integrated into a single, multidimensional conceptualization. Three, that whereas most earlier research related to driving behaviors associated with crashes, it is important to broaden the scope to include characteristics of driving in general in order to understand the whole range of variables that predict how people drive, including safe, careful, and considerate behaviors.

This approach led to the design of a scale assessing four differentiated driving styles: (1) reckless and careless; (2) anxious; (3) angry and hostile; and (4) patient and careful. The *reckless and careless style* refers to deliberate violations of safe driving norms and the seeking of sensations and thrills while driving. It is the most salient reflection of risky driving behavior, characterized by driving at high speeds, passing in no-passing lanes, and driving while intoxicated. The *anxious style* relates to feelings of vigilance, nervousness, and tension, as well as ineffective engagement in relaxing activities during driving. This style characterizes people who feel unsure of themselves as drivers, and reflects their sense of helplessness and insecurity. The *angry and hostile style* refers to expressions of

irritation, rage, and hostility on the road, such as cursing other drivers, honking the horn, or flashing headlights. It indicates aggression accompanied by a motivation to beat out other vehicles in competitive traffic situations. The *patient and careful style* relates to well-adjusted driving behaviors, such as planning ahead, paying full attention to the road, displaying patience, courtesy, and calm behind the wheel, and obeying the traffic rules. It characterizes drivers who are considerate and sympathetic to other drivers' needs, and who exhibit understanding of complex traffic situations.

Initial studies revealed eight coherent, valid, and reliable factors that could be grouped into these four global styles (Taubman – Ben-Ari et al., 2004): risky and high velocity driving (reckless and careless style); anxious, dissociative, and distress reduction driving (anxious style); angry and hostile driving; and careful and patient driving. Most subsequent studies have therefore used the four-factor version of the inventory. However, reasonable to high reliabilities and good validity have been found for both the four global styles and the eight factors. In addition, some adaptations of the MDSI contain six factors.

The MDSI has been translated into numerous languages (among them, Italian, Spanish, Romanian, and Mandarin Chinese), and used in various countries (e.g., Australia, England, Italy, Argentina, Spain, the United States, the Netherlands, Switzerland). It has been culturally adapted for Argentina (Poó and Ledesma, 2013; Trógolo et al., 2020), Spain (Padilla et al., 2020), Romania (Holman and Havârneanu, 2015), and China, where two different versions have been developed (Sun and Chang, 2019; Wang et al., 2018). It has also been validated in the Netherlands and the Flemish-speaking region of Belgium (Hooft van Huysduynen et al., 2015), Malaysia (Karjanto et al., 2017), Bulgaria (Totkova and Racheva, 2019), and Italy (Freuli et al., 2020), as well as among professional drivers in Colombia (Useche et al., 2019b). Overall, the results of these studies attest to the universal applicability and robustness of the inventory.

Sociodemographic and Driving-related Variables

Most of the sociodemographic characteristics examined over the years have not yielded significant associations with the four driving styles. This suggests that driving styles are not affected by background variables such as education, health, economic status, or family status, but rather represent relatively stable and universal traits. However, findings do show quite systematically that gender is a strong predictor of driving styles, with men engaging in the reckless and careless and the angry and hostile styles more than women, and women adopting the careful and patient style more than men. Age appears to play a role as well, so that the three maladaptive driving styles tend to lessen over the years, whereas the careful and patient style becomes more dominant as people get older (Taubman – Ben-Ari and Skvirsky, 2016).

In regard to driving-related variables, all the indicators of risky driving (e.g., involvement in car crashes, number of traffic violations, assessment of risky driving as dangerous), whether assessed by self-report techniques or by the use of a simulator or a car equipped with an in-vehicle data recorder (IVDR), have been found to be coherently and systematically related to the MDSI driving styles in the expected directions. These findings not only indicate that maladjusted driving is associated with a higher frequency of risky behaviors on the road, but also provide validation of the MDSI as an efficient measurement tool. This is valuable information, enabling the inventory to be used to identify baseline driving styles before road safety interventions, as well as for post-intervention assessment. It may also be employed to enhance drivers' awareness of their own and others' driving styles, either by clinicians in individual or family sessions or by safety officers as part of programs aimed at effecting organizational culture change. The MDSI can therefore inform the efforts of those striving to enhance traffic safety at all stages of their work: planning, dissemination, and assessment.

Following are the background variables associated with each of the driving styles.

Reckless and careless style: Men are systematically found to engage in the reckless and careless driving style more than women (e.g., Holland et al., 2010; Navon and Taubman – Ben-Ari, 2019; Padilla et al., 2020; Poó and Ledesma, 2013; Pugnetti and Elmer, 2020; Sun and Chang, 2019; Taubman – Ben-Ari, 2018; Taubman – Ben-Ari and Yehiel, 2012). Similar results have been yielded by lower age (e.g., Farah et al., 2007; Gwyther and Holland, 2012; Hooft van Huysduynen et al., 2018; Taubman – Ben-Ari et al., 2004; Taubman – Ben-Ari and Yehiel, 2012). In addition, drivers who have been involved in any kind of car crash consistently score higher on this style than those who have not (Liang and Lin, 2018; Poó et al., 2013; Sun and Chang, 2019; Taubman – Ben-Ari et al., 2004; Taubman – Ben-Ari and Skvirsky, 2016), as do drivers with a history of traffic violations or who report both ordinary and aggressive violations in questionnaires such as the DBQ (e.g., Holman and Popusoi, 2018; Liang and Lin, 2018; Padilla et al., 2020; Sun and Chang, 2019; Wang et al., 2018). Along the same lines, reoffenders endorse the reckless and careless style more than non-offenders (Faílde-Garrido et al., 2016; Padilla et al., 2020), and the rate of occupational driving crashes in the previous two years among professional drivers was significantly and positively linked to this driving style (Useche et al., 2019b).

The same picture emerges from a set of self-report relevance assessments. Thus, both self-reported **risky driving habits** and the **willingness of drivers to take risks while driving** were positively associated with the reckless and careless style, while an inverse association was found between this style and the **assessment of reckless driving as risky** (Taubman – Ben-Ari and Skvirsky, 2016).

Exposure, or the average amount of time the individual drives on a regular basis, has also been related to this driving style. Higher exposure has been positively associated with high speed driving, suggesting that the more time a person spends behind the wheel, the greater their tendency to drive recklessly (Holland et al., 2010). This might be related to the finding that young drivers who have their own car report higher reckless and careless driving than those who do not own a car (Taubman – Ben-Ari and Skvirsky, 2016). However, as with age, driving experience, that is the length of time the individual has had a driving license, appears to moderate risky driving, correlating negatively with the reckless and careless style (Gwyther and Holland, 2012; Taubman – Ben-Ari, 2018).

Furthermore, the reckless and careless style has been found to correlate with **performance measures** collected in a driving simulator (e.g., Bellem et al., 2018; Farah et al., 2007). Higher scores on this style were positively associated with speed, number of completed passing maneuvers, critical gaps (Farah et al., 2007), speeding, braking, steering, lateral positioning, and maintaining distance from the vehicle ahead (Hooft van Huysduynen et al., 2018). Similarly, this style corresponded with real driving data collected by an IVDR, correlating positively with the rate of risky events recorded (Taubman – Ben-Ari, Eherenfreund-Hager et al., 2016). Finally, lower hazard perception in various domains, such as social, financial, and health, has been associated with higher reckless and careless driving (Padilla et al., 2020).

Anxious style: Women tend to endorse the anxious style more than men (e.g., Holland et al., 2010; Poó and Ledesma, 2013; Poó et al., 2013; Sun and Chang, 2019; Taubman – Ben-Ari, 2006, 2014a). In addition, a negative association has been found between age and the anxious style (e.g., Navon and Taubman – Ben-Ari, 2019; Taubman – Ben-Ari et al., 2004), and its dissociative component in particular (Trógolo et al., 2014).

Drivers who had committed **traffic violations** also scored higher on this style than those who had not or those who reported fewer violations, (e.g., Padilla et al., 2020; Sun and Chang, 2019; Wang et al., 2018). In the same vein, DBQ ordinary violations (Holman and Popusoi, 2018), aggressive violations, and errors and lapses (Wang et al., 2018) were all positively associated with the anxious driving style, as was dissociative driving, which correlates substantively and positively with the DBQ subscales Lapses and Errors (Padilla et al., 2020). Similarly, both younger and older drivers who had been involved in a **car crash** resulting in fatalities reported higher anxious driving than those without this history (Taubman – Ben-Ari and Skvirsky, 2016). On the other hand, higher **exposure** (e.g., Gwyther and Holland, 2012; Holland et al., 2010) and lower **experience** (e.g., Holman and Havârneanu, 2015; Karjanto et al., 2017; Sun and Chang, 2019) have been associated with the anxious driving style, indicating that the more a person drives and the more experience they have behind the wheel, the less anxious their driving.

In regard to **performance measures**, higher critical passing gaps in a driving simulator were found among drivers scoring higher on the anxious style (Farah et al., 2007). This style also correlated negatively with the rate of risky events recorded by an IVDR (Taubman – Ben-Ari, Eherenfreund-Hager et al., 2016). However, self-reported **risky driving habits** have been positively associated with the anxious driving style (Taubman – Ben-Ari and Skvirsky, 2016).

Angry and hostile style: Men report driving in this manner more than women (e.g., Poó et al., 2013; Padilla et al., 2020; Pugnetti and Elmer, 2020; Taubman – Ben-Ari, 2006, 2018), and lower age is consistently associated with higher endorsement of the angry and hostile driving style (e.g., Farah et al., 2007; Gwyther and Holland, 2012; Navon and Taubman – Ben-Ari, 2019; Sun and Chang, 2019; Taubman – Ben-Ari, 2014a). Furthermore, drivers who had committed **traffic violations** and been involved in **car crashes** scored significantly higher on this style (e.g., Liang and Lin, 2018; Padilla et al., 2020; Poó et al., 2013; Sun and Chang, 2019; Taubman – Ben-Ari and Skvirsky, 2016), including professional drivers (Useche et al., 2019b, 2020). Similarly, higher scores on both DBQ ordinary and aggressive violations were associated with the angry and hostile style (Holman and Popusoi, 2018; Wang et al., 2018), and traffic reoffenders scored higher on this style than nonoffenders (Padilla et al., 2018, 2020).

In addition, a set of self-report measures relating to driving revealed a negative association between this style and the **assessment of reckless driving as risky**, and positive associations with the reported frequency of **risky driving habits** and **willingness to take risks while driving** (Taubman – Ben-Ari and Skvirsky, 2016). Driving **experience** also correlated negatively with the angry and hostile style (Gwyther and Holland, 2012). As to **performance measures**, participants with lower critical passing gaps in a driving simulator scored higher on this driving style (Farah et al., 2009), and the rate of risky events assessed by an IVDR was positively associated with the angry and hostile style (Taubman – Ben-Ari, Eherenfreund-Hager et al., 2016).

Patient and careful style: Women tend to endorse the patient and careful style more than men (e.g., Holland et al., 2010; Poó and Ledesma, 2013; Pugnetti and Elmer, 2020; Taubman – Ben-Ari, 2018; Taubman – Ben-Ari and Yehiel, 2012), and it has also been related to older age (e.g., Hooft van Huysduynen et al., 2018; Padilla et al., 2020; Poó et al., 2013; Sun and Chang, 2019; Taubman – Ben-Ari and Yehiel, 2012). In addition, this style has been associated with lower previous involvement in **car crashes** (Poó et al., 2013; Sun and Chang, 2019; Taubman – Ben-Ari et al., 2004; Taubman – Ben-Ari and Skvirsky, 2016), and fewer self-reported driving violations (Fáilde-Garrido et al., 2016; Holman and Popusoi, 2018; Wang et al., 2018), with non-offenders scoring higher than others (Padilla et al., 2018, 2020). Moreover, the patient and careful style correlated positively with the DBQ positive driving behaviors and negatively with the dangerous driving behaviors (Padilla et al., 2020; Wang et al., 2018). Higher **assessment of reckless driving as risky** and lower **risky driving habits** and **willingness to take risks behind the wheel** have also been associated with the patient and careful style (Taubman – Ben-Ari and Skvirsky, 2016). In line with these findings, in an on-road experiment examining when drivers choose to deactivate full-range adaptive cruise control (ACC), Varotto et al. (2018) found that patient and careful drivers resumed manual control or regulated the target speed when the sense of risk was higher in low-risk situations and lower in high-risk situations. Thus, risk perceptions were related to this driving style not only when measured by self-report instruments, but also in simulated driving.

Higher **exposure** has been negatively associated with the patient and careful style (Holland et al., 2010), indicating that the more a person drives, the less patient their driving. However, driving **experience** has yielded a positive association with this style (Gwyther and Holland, 2012; Holman and Havârneanu, 2015; Karjanto et al., 2017; Sun and Chang, 2019), suggesting that over the years a person's driving tends to become more patient and careful (Taubman – Ben-Ari and Skvirsky, 2016). In regard to **performance measures**, higher critical passing gaps in a simulator were found among drivers scoring higher on the patient and careful style (Farah et al., 2007), and the rate of risky events recorded by an IVDR correlated negatively with this style (Taubman – Ben-Ari, Eherenfreund-Hager et al., 2016).

MDSI and Personality

The question of the associations between the MDSI factors and personality traits, cognitive skills, and emotional characteristics has also aroused the interest of researchers. Some of the variables investigated are directly connected to risky behavior or aggressive tendencies, both validating the relevant driving styles and deepening our understanding of their fundamental premises. Others are more distal, enabling us to extend what can be observed and understood from external behavior to the underlying motivations and deeper levels of the self that lead to the choice of a particular driving style. The associations found between personal variables and each of the driving styles are presented below.

Reckless and careless style: This mode of driving reflects a maladaptive approach by which individuals consciously choose to take risks to achieve enjoyment and arousal. It is usually accompanied by positive affect stemming from the pleasure and gratification generated by the thrills and excitement of the driving experience. Thus, this style, which endangers both the driver and other road users, is spurred by a self-focused motivation (Taubman – Ben-Ari, 2008) reflected in the desire to satisfy one's ever-growing need for sensations. Self-esteem, sense of coherence, and differentiation of self, which represent adaptive and healthy personality traits (Antonovsky, 1979; Bowen, 1978; Rosenberg, 1979), have all been inversely associated with the reckless and careless driving style (Miller and Taubman – Ben-Ari, 2010; Taubman – Ben-Ari, 2014a; Taubman – Ben-Ari et al., 2004). Significant inverse correlations have also been found between this style and the Big Five dimensions (John and Srivastava, 1999) of agreeableness and conscientiousness (Taubman – Ben-Ari and Yehiel, 2012; Wang et al., 2018). In contrast, sensation seeking, which is frequently associated with risky behaviors, has been positively related to the endorsement of this style among both younger and older drivers (Holman and Havârneanu, 2015; Karjanto et al., 2017; Sun and Chang, 2019; Poó and Ledesma, 2013; Taubman – Ben-Ari et al., 2004; Taubman – Ben-Ari and Skvirsky, 2016), and especially among young men (Miller and Taubman – Ben-Ari, 2010; Poó and Ledesma, 2013). Similarly, positive correlations have been found between the reckless and careless driving style and the aggression–hostility personality trait (Poó and Ledesma, 2013), impulsivity (Totkova 2020), and sensitivity to reward, all of which are indications of intense sensation seeking (Padilla et al., 2020). Other traits positively associated with the reckless and careless style relate to difficulty regulating emotional states, such as impulse control difficulties (Navon and Taubman – Ben-Ari, 2019; Trógolo et al., 2014), nonacceptance of emotional responses, and difficulties engaging in goal-directed behavior (Trógolo et al., 2014). Moreover, emotion regulation was found to play an important role in explaining why young drivers tend to engage in this driving style, with the younger the driver, the more they reported emotion regulation difficulties, and the more they reported emotion regulation difficulties, the more they tended to drive recklessly (Navon-Eyal and Taubman – Ben-Ari, 2020). In addition, lower trait forgivingness, which reflects a difficulty regulating negative emotions, contributed to a higher reported tendency to drive recklessly (Navon and Taubman – Ben-Ari, 2019).

Finally, among young drivers, general conformity with authority has been inversely related to the reckless and careless style (Taubman – Ben-Ari and Katz-Ben-Ami, 2012). In other words, drivers endorsing this style tend to focus on fulfilling their desire for adventure and the immediate gratification of their needs, coupled by a lack of respect for authority and the law.

Anxious style: This is another maladaptive driving style that endangers the driver and other road users, but for completely different reasons. Paradoxically, it is motivated by the need to protect the self along with the fear of others' behavior. Anxious drivers are characterized by hesitation and the inability to make effective decisions. They lack confidence in their driving skills, and view other drivers as an additional source of stress (Taubman – Ben-Ari, 2008). The personality characteristics found to correlate positively with the anxious driving style include: trait anxiety and neuroticism, which are basic signs of psychological imbalance (Miller and Taubman – Ben-Ari, 2010; Poó and Ledesma, 2013; Taubman – Ben-Ari et al., 2004; Taubman – Ben-Ari and Yehiel, 2012); external locus of control (Holland et al., 2010), which refers to the belief that the outcomes of events are controlled by external forces, such as fate, luck, or powerful others (Rotter, 1966); higher alcohol dependence (Padilla et al., 2020); sensitivity to punishment, which is a reflection of a greater sensitivity to the possible dangers of the road (Padilla et al., 2020); and impulsive sensation seeking, which has been associated in particular with the dissociative and distress reduction components of this driving style (Holman and Havârneanu, 2015; Poó and Ledesma, 2013). In contrast, personality characteristics considered constructive resources have been shown to correlate inversely with the anxious style. These include self-esteem (associated with the dissociative component; Taubman – Ben-Ari et al., 2004), extraversion (Taubman – Ben-Ari et al., 2004), the Big Five dimension of conscientiousness (Taubman – Ben-Ari and Yehiel, 2012; Wang et al., 2018), and desire for control (Holman and Havârneanu, 2015; Karjanto et al., 2017). Among young drivers, sense of coherence (Taubman – Ben-Ari, 2014a) and perceived self-efficacy as a driver (Miller and Taubman – Ben-Ari, 2010) have also yielded inverse associations with anxious driving.

More impulse control difficulties and limited access to emotion regulation strategies, two dimensions of emotional dysregulation (Gratz and Roemer, 2004), have also been associated with higher anxious driving (Navon and Taubman – Ben-Ari, 2019), as have lack of emotional awareness, lack of emotional clarity, nonacceptance of emotional response, difficulties engaging in goal-directed behavior, and limited access to emotion regulation strategies. In addition, emotion regulation fully mediated between age and the anxious driving style, so that the younger the driver, the more they reported emotion regulation difficulties, which in turn was related to higher endorsement of the anxious style (Navon-Eyal and Taubman – Ben-Ari, 2020). Finally, lower trait forgivingness contributed to a higher reported tendency to drive in the anxious style (Navon and Taubman – Ben-Ari, 2019). Anxious drivers are therefore impelled by their fears and lower ego resources.

Angry and hostile style: This style, which is also maladaptive, relates to aggressive driving and the desire to compete with other road users, who are considered less competent. It is expressed in violent behavior on the road accompanied by negative emotions such as anger, antagonism, rage, nervousness, and irritability. Although the driving behavior represented by this style may resemble

that of the reckless and careless style, the difference lies in the underlying motivation. Here the driver is not looking for excitement, but is fulfilling a need to win out over others and vent frustrations (Taubman – Ben-Ari, 2008). Thus, it is not a reflection of happiness and pleasure, but of anger and impatience. Angry and hostile driving has yielded positive correlations with driving anger dimensions (as measured by three factors: traffic obstructions, illegal behavior, and hostile gestures; Padilla et al., 2020), sensation seeking (Holman and Havârneanu, 2015; Miller and Taubman – Ben-Ari, 2010; Poó and Ledesma, 2013), the aggression–hostility personality trait (Poó and Ledesma, 2013), higher difficulties in impulse control (Navon and Taubman – Ben-Ari, 2019; Trógolo et al., 2014), higher desire for control (Taubman – Ben-Ari et al., 2004), and the Alcohol Dependence Syndrome (Padilla et al., 2020). Inverse correlations have been found with the Big Five factors of agreeableness and conscientiousness (Taubman – Ben-Ari and Yehiel, 2012), forgivingness (Navon and Taubman – Ben-Ari, 2019), sense of coherence, and perception of meaning in life (Taubman – Ben-Ari, 2014a). Moreover, difficulties regulating emotions fully mediated between age and this style, so that the younger the driver, the more they reported emotion regulation difficulties, which in turn was associated with higher endorsement of the angry and hostile style (Navon-Eyal and Taubman – Ben-Ari, 2020).

Thus, drivers adopting the angry and hostile style are both aggressive and easily irritated, and have less faith in the benevolence of the world. They are impatient of other drivers or complex traffic situations, and tend to react both impulsively and vehemently.

Careful and patient style: This is an adaptive and positive driving style that represents commitment to safety, higher values of caring and empathy for others and the environment, and respect for the law. Careful drivers are motivated by conscientiousness, consideration, and awareness of the consequences of their driving for other road users. Emotions are rarely involved in this driving style. Instead, it is regulated by systematic planning ahead, self-control and restraint (Taubman – Ben-Ari, 2008), and low emotional conflicts or difficulties (Navon-Eyal and Taubman – Ben-Ari, 2020). The careful style has been positively related to self-esteem, desire for control (Holman and Havârneanu, 2015; Karjanto et al., 2017; Taubman – Ben-Ari et al., 2004), differentiation of self (especially among young female drivers; Miller and Taubman – Ben-Ari, 2010), the Big five factors of agreeableness, conscientiousness, and openness (Taubman – Ben-Ari and Yehiel, 2012; Wang et al., 2018), sense of coherence (Taubman – Ben-Ari, 2014a), and higher forgivingness (Navon and Taubman – Ben-Ari, 2019). It has also been associated with greater perception of meaning in life (Taubman – Ben-Ari, 2014a), and a higher ethical stance of idealism (Holman and Popusoi, 2018), reflecting the principle that a morally correct action will always result in a positive outcome for others, and therefore leading to a reluctance to break rules (Forsyth, 1992). Among young drivers, it has also been associated with higher perceived self-efficacy as a driver (Miller and Taubman – Ben-Ari, 2010).

In contrast, careful driving has been shown to correlate inversely with sensation seeking (Holman and Havârneanu, 2015; Poó and Ledesma, 2013; Taubman – Ben-Ari et al., 2004), impulsivity (Totkova, 2020), trait anxiety and neuroticism (Taubman – Ben-Ari et al., 2004), and the emotion regulation dimensions of difficulties with impulse control and emotional awareness (Navon and Taubman – Ben-Ari, 2019; Trógolo et al., 2014). In other words, drivers displaying this style drive safely due not only to their tendency to obey traffic laws, but also to their idealism, values of prudent driving, care for others, and the tendency to be positive and considerate.

MDSI and Familial and Social Contexts

The third set of variables that has been examined in relation to the MDSI are environmental spaces in which driving takes place, including the family as a whole, individual family members (parents, siblings, grandparents), peers, and friends. This issue is relevant mainly to young drivers, as it relates to the context in which their driving style is shaped during their early experience behind the wheel.

Most investigations of family members have focused on the influence of the parents, and have produced considerable evidence of the intergenerational transmission of driving styles (Gil et al., 2016; Miller and Taubman – Ben-Ari, 2010; Taubman – Ben-Ari et al., 2005). This suggests that parents represent a model for their offspring, probably from early childhood, when children observe their parents' driving behavior long before they themselves have a license (Taubman – Ben-Ari, 2014b).

In addition to modeling, the general atmosphere in the family has also been related to the children's driving styles. Hence, studies have shown that the higher the family's level of cohesion and adaptability (two aspects of Olson's FACES; Olson, 1991), the lower the young driver's tendency to endorse any of the three maladaptive styles and the higher their preference for the careful and patient style (Gil et al., 2016; Taubman – Ben-Ari and Katz-Ben-Ami, 2013).

A third component of the parent-child relationship that has been examined extensively in this context is the multidimensional concept of Family Climate for Road Safety (FCRS; Taubman – Ben-Ari and Katz-Ben-Ami, 2013), which relates to seven dimensions of the family's influence on teens' driving habits: Modeling, Feedback, Communication, Monitoring, Commitment to Safety (represented negatively in the Family Climate for Road Safety Scale as Noncommitment to Safety), Messages, and Limits. Studies reveal that all positive aspects of FCRS are inversely associated with the reckless and careless style among young drivers, whereas higher family's lack of commitment to safety is positively related to this style (Skvirsky et al., 2017; Taubman – Ben-Ari and Katz-Ben-Ami, 2012, 2013). Furthermore, noncommitment to safety and messages were found to mediate the relationship between the family's perceived cohesion and father's reckless and anxious driving styles on the one hand, and novice male drivers' driving styles on the other. More specifically, higher endorsement of the reckless and careless style by fathers and family relations characterized by lower cohesion were related to young drivers' greater perception of the family as uncommitted to safety. This, in turn, was associated with higher endorsement of both the reckless and careless and the angry and hostile styles, as well as a lower preference for the patient and careful style, on the part of the young driver (Gil et al., 2016).

Reckless and careless style: Father–son dyads produced the strongest associations in this style, indicating the likelihood that the sons of fathers who model reckless driving will adopt the same style (Taubman – Ben-Ari, 2016). Examination of FCRS among parents of young drivers showed that their own reckless and careless driving style correlated inversely with the positive aspects of family climate, and positively with noncommitment to safety (Taubman – Ben-Ari, 2015). Moreover, negative correlations were found between parents' positive FCRS dimensions and the reckless and careless style reported by their children, while a positive association emerged between parents' noncommitment to road safety and their children's reckless driving style (Taubman – Ben-Ari, 2016).

In addition, a study of young drivers who also reported on their older siblings' driving style (Taubman – Ben-Ari, 2018) found that the higher the young driver perceived their sibling to exhibit the reckless and careless style, the higher their own endorsement of this manner of driving, with both adopting it to a similar degree. Furthermore, the higher the siblings' conflictual relationship, the more the young driver tended to adopt the reckless and careless driving style.

In a study investigating the issue of grandparents (Taubman – Ben-Ari, Findler et al., 2016), higher endorsement of the reckless driving style was significantly related to higher grandparents' reports of tension when driving their grandchildren, as well as to less positive attitudes to the use of child restraints.

Peer pressure is also linked to the reckless and careless style of young drivers, so that greater attentiveness to peers was associated with higher maladaptive driving and lower safety (Taubman – Ben-Ari and Katz-Ben-Ami, 2012). Moreover, lower peer commitment to safe driving was related to this driving style (Skvirsky et al., 2017).

Anxious style: Intergenerational transmission has been found for this manner of driving as well (Gil et al., 2016; Miller and Taubman – Ben-Ari, 2010; Taubman – Ben-Ari et al., 2005). In addition, the higher the family's level of cohesion and adaptability (Olson, 1991), the lower the young driver's tendency to drive anxiously (Gil et al., 2016; Taubman – Ben-Ari and Katz-Ben-Ami, 2013). The anxious driving style was also found to correlate positively with the FCRS dimensions of monitoring and limits (Taubman – Ben-Ari and Katz-Ben-Ami, 2012, 2013), indicating that firm discipline on the part of parents does not guarantee the adaptive behavior of their children, but rather leads to greater anxiety and nervousness on the road. Links have also been found between the anxious style and a lower tendency in the family to communicate and set boundaries for young drivers (Skvirsky et al., 2017). Moreover, among parents of young drivers, the positive FCRS dimensions (save for monitoring) correlated inversely both with their own anxious style (Taubman – Ben-Ari, 2015), and with their offspring's anxious driving (Taubman – Ben-Ari, 2016). Finally, a positive association was found between parents' noncommitment to road safety and their children's adoption of the anxious driving style (Taubman – Ben-Ari, 2016).

Young drivers' self-reported anxious style was similarly associated with their perception that their sibling drove in this manner. Here the young driver showed an even higher level of anxiety behind the wheel than their older sibling. Relations between the two played a role in this driving style as well: the warmer and closer the relationship, the lower the young drivers' anxious driving, while the more conflictual the relationship, the greater their tendency to drive anxiously (Taubman – Ben-Ari, 2018).

Furthermore, here too, anxious driving style was significantly related to higher grandparents' reports of tension when driving their grandchildren, and to less positive attitudes to the use of child restraints (Taubman – Ben-Ari, Findler et al., 2016).

Higher peer pressure (Skvirsky et al., 2017; Taubman – Ben-Ari and Katz-Ben-Ami, 2012) and perceived social costs of driving with friends (Skvirsky et al., 2017) were also positively associated with the anxious driving style among young drivers.

Angry and hostile style: Evidence of intergenerational transmission of the angry and hostile driving style (Gil et al., 2016; Miller and Taubman – Ben-Ari, 2010; Taubman – Ben-Ari et al., 2005), as well as the influence of the general atmosphere in the family, has also been found. Hence, studies have shown that the higher the family's level of cohesion and adaptability, and the higher the positive aspects of FCRS, the lower the young driver's tendency to endorse this style (Gil et al., 2016; Taubman – Ben-Ari and Katz-Ben-Ami, 2013). The angry and hostile style has also been related to a lower level of communication and feedback in the family and a lack of its commitment to safe driving (Skvirsky et al., 2017; Taubman – Ben-Ari, 2016). For this style as well, positive correlations emerged between siblings (Taubman – Ben-Ari, 2018), and a more conflictual relationship between them was associated with higher angry driving among young drivers.

The angry and hostile driving style was also related to higher grandparents' reports of tension when driving their grandchildren, and less positive attitudes to child restraints (Taubman – Ben-Ari, Findler et al., 2016). In addition, among young drivers, this style was positively associated with peer pressure (Taubman – Ben-Ari and Katz-Ben-Ami, 2012) and with a lack of commitment to safe driving by peers (Skvirsky et al., 2017).

Careful and patient style: Intergenerational transmission of the careful driving style has been observed as well (Gil et al., 2016; Miller and Taubman – Ben-Ari, 2010; Taubman – Ben-Ari et al., 2005). This is an important indication of the positive effect parents can have on their children's driving habits. Similarly, a positive atmosphere in the family, that is, a high level of cohesion and adaptability, has been related to a higher preference for the careful and patient style among young drivers (Gil et al., 2016; Taubman – Ben-Ari and Katz-Ben-Ami, 2013). Furthermore, the positive aspects of FCRS have been associated with the careful driving style, along with a negative correlation with noncommitment to safety (Taubman – Ben-Ari and Katz-Ben-Ami, 2012, 2013).

As with the other driving styles, the careful and patient style is shared among siblings (Taubman – Ben-Ari, 2018), and was found to correlate with a warm and close relationship between them. Thus, a positive relationship between siblings can be considered a protective element, similar to that of parents who drive in this style.

In addition, endorsement of the careful driving style among grandparents was associated with grandparents' positive attitude to child restraints (Taubman – Ben-Ari, Findler et al., 2016). This style was correlated among young drivers with lower peer pressure (Skvirsky et al., 2017; Taubman – Ben-Ari and Katz-Ben-Ami, 2012). Another interesting finding is reported by a study using the

MDSI in New Zealand: with a passenger in the car, drivers were less reckless, less angry, and more patient, all of which are features conducive to safer driving (Charlton and Starkey, 2020).

Appendix 1: Examples of Studies Using the MDSI

<i>Authors and year of publication</i>	<i>Country</i>	<i>Language</i>	<i>Version, Number of items and driving styles</i>
Taubman – Ben-Ari et al. (2004)	Israel	Hebrew	Original version; 44 items; eight driving styles: dissociative, anxious, risky, angry, high velocity, distress reduction, patient, careful
Taubman – Ben-Ari et al. (2005).	Israel	Hebrew	Original version; 44 items; four driving styles: reckless and careless, anxious, angry and hostile, patient and careful
Holland et al. (2010)	UK	English	Original version; 44 items; eight driving styles: dissociative, anxious, risky, angry, high velocity, distress reduction, patient, careful
Rossi et al. (2012)	Italy	Italian	Original version; 44 items; four driving styles: reckless and careless, anxious, angry and hostile, patient and careful
Freuli et al. (2020)	Italy: validation study	Italian	Original version; 40 items; eight driving styles: dissociative, anxious, risky, angry, high velocity, distress reduction, patient, careful
Poó et al. (2013)	Argentina: validation of MDSI-S	Spanish	Version translated into the Spanish spoken in Argentina and adapted to the Argentinian sociocultural driving context (MDSI-S); 40 items, of which 17 are Argentinian additions; six driving styles: risky, dissociative, angry, careful, anxious, distress reduction
Faílde-Garrido et al. (2016)	Spain	Spanish	MDSI-S; 40 items; six driving styles: risky, dissociative, angry, careful, anxious, distress reduction
Useche et al. (2019a)	Colombia	Spanish	MDSI-S; 40 items; six driving styles: risky, dissociative, angry, careful, anxious, distress reduction
Useche et al. (2019b)	Colombia: validation of the MDSI for professional drivers	Spanish	Original version adapted and validated for professional drivers; 33 items; four driving styles: reckless and careless, anxious, angry and hostile, patient and careful
Padilla et al. (2020)	Spain: validation of MDSI-Spain	Spanish	Version adapted to the Spanish spoken in Spain (MDSI-Spain); 34 items, 23 of which were taken from the Argentinian version; six driving styles: reckless, anxious, careful, angry, dissociative, distress reduction
Hooft van Huysduynen et al. (2015)	Netherlands and Belgium: validation study	English and Dutch	Adapted version of original inventory; 24 items; five driving styles: careful (including items from the risky style), angry, anxious, dissociative, distress reduction
Holman and Havârneanu (2015)	Romania: validation of MDSI-RO	Romanian	Version translated into Romanian and adapted for Romanian socio-cultural driving context (MDSI-RO); 41 items (including 5 Romanian additions tapping the Romanian-specific norms of violation of rules as an irrational driving style), and 36 items corresponding to items in previous versions found to be culturally equivalent in the Romanian context; seven driving styles: anxious, patient and careful, risky, angry, distress reduction, dissociative, irrational
Karjanto et al. (2017)	Malaysia		Adapted version used in the Netherlands; 24 items; four driving styles: careful, risky, anxious-dissociative, angry
Skvirsky et al. (2017)	Australia	English	Original version; 44 items; four driving styles: reckless and careless, anxious, angry and hostile, patient and careful
Bellem et al. (2018)	Germany	German	Original version; 44 items; eight driving styles: dissociative, anxious, risky, angry, high velocity, distress reduction, patient, careful
Wang et al. (2018).	China: validation of MDSI-C	Mandarin Chinese	Brief version translated into Mandarin Chinese (MDSI-C), developed from original MDSI, MDSI-S, and MDSI-RO; 12 items; four driving styles: risky, angry-high velocity, careful, anxious
Sun and Chang (2019)	China: validation of MDSI-C	Mandarin Chinese	Version translated into Mandarin Chinese and adapted for China; 32 items, of which 30 are from the original inventory, and 2 items are added to the risky driving style; six driving styles: risky, anxious, angry, distress reduction, careful, dissociative
Totkova and Racheva (2019)	Bulgaria: validation of MDSI-BG	Bulgarian	Version translated into Bulgarian and adapted for the sociocultural driving context of Bulgaria (MDSI-BG); 57 items, of which 44 items are from the original inventory, 12 from the Argentinian version, and 7 from the Romanian version; eight driving styles: risky, anxious, high velocity, dissociative, patient and careful, angry, distress reduction, irrational

Introduction

The aim of this chapter is to give an overview of the state of the art concerning the role of transport risk perception for driving behavior, demand for risk mitigation, and use of sustainable urban transport modes. The review summarizes theory and peer-reviewed empirical findings regarding risk perception and transport. Transport is delimited to surface modes typically available in urban areas, such as car, tram, metro, walking, and cycling. Risk perception is also important in sectors such as aviation and shipping, but this is beyond the scope of the current review.

As shown in **Fig. 1**, the review is divided into four sections. The first section discusses the risk perception concept with a focus on operational definition and theoretical foundations. The second section focuses on risk perception in relation to an important variable specifically in the road traffic system, namely driving behavior. The third section broadens the scope to the entire surface transport system, and focuses on risk perception in relation to demand for transport risk mitigation exerted by the public upon the transport authorities. The last section maintains this scope, but with a particular focus on transport mode use in urban areas. This section discusses risk perception in relation to general and active sustainable mode use in urban areas and, more specifically, mode choices on school trips. The latter concerns risk perception among parents when they choose transport modes for their children on school travels. This focus is viable as children represent the next generation of mode users and transport habits are usually developed in young age (see, e.g., [Verplanken et al., 1997](#); [Verplanken and Orbell, 2003](#)).

What is Transport Risk Perception?

In research, risk perception has been conceived as an endogenous as well as exogenous variable. The first-mentioned type of research concerns which factors that may influence on the “level” of perceived risk, and the last-mentioned focuses on whether perceived risk is associated with lay peoples’ demand for risk mitigation, choice of travel mode, and risk-taking behavior in traffic. In addition, there has been attention on the concept and how it should be measured. The current review will mainly focus on risk perception as exogenous variable as the concept primarily is interesting because it predicts transport behavior.

Definition and Measurement of Transport Risk Perception

The psychometric approach previously dominated risk perception research. It focused on the unique and subjective qualities of perceived risk ([Slovic, 1992, 2000](#)). [Fischhoff et al. \(1978\)](#) showed that risk sources had a pattern of qualities and that these qualities were related to perceived risk. Nine general properties of the risk source were found to be important; volunteerism of risk, immediacy of effect, knowledge about the risk by the person who was exposed to the potentially-hazardous risk source, knowledge about the risk in science, control over the risk, newness, whether the risk was chronic/catastrophic, was common/dread, and how severe the consequences were judged to be. The degree to which these factors were related to potentially hazardous activities or technologies

Figure 1 Chapter outline.

was believed to determine how the risk source was perceived (Fischhoff et al., 2000). Principal component analysis (PCA) of the nine properties across a large number of risk sources showed that dread and severity of consequences were the most important dimensions. The last-mentioned dimension concerned the evaluation of the probability that a mishap or illness would be fatal. Accordingly, the last-mentioned property should be considered as a measure of the perceived probability of a fatal incident occurring, that is, judgment of severity of consequences.

Risk perception is often considered to be a pure cognitive construct. It can be argued that dread reflects emotion (Sjøberg, 1999). Emotions, such as worry and concern, should therefore be seen as an effect of perceived risk rather than a part of the construct. Precognitive processes, for example, anticipated worry, may in accordance with the risk-as-feeling approach (Loewenstein et al., 2001) influence perception of risk. “Risk-as-feelings” may be distinguished from “risk-as-analysis” (Slovic et al., 2001). Risk-as-analysis is the process where cognitive reasoning, reflection and logic are used to evaluate a risk source. This process is identical to perceived risk. The risk-as-feelings framework (Loewenstein et al., 2001) refers to intuitive and instinctive reactions to a risk source. Consequently, emotions such as worry and concern are relevant for risk perception, however, primarily because they can influence and be influenced by cognitive evaluations, that is, of perceived risk. Perception of risk as a construct applies only to cognitively mediated processes. In accordance with the studies mentioned above, risk perception is most frequently understood to be the subjective assessment of the probability of an accident or any other event with negative consequences and the anticipated judgement of severity of consequences if such an event should take place (see, e.g., Bubek et al., 2012; Champ and Brenkert-Smith, 2016; Sjøberg, 1998, 2004). Thereby, we define transport risk perception by subjective evaluations of probability and potential severity of consequences of accidents or security incidents in transport.

The focus on the measurement of subjective assessment of probability and judgement of severity of consequences is in accordance with the two main factors in Quantitative Risk Assessments (QRAs). In addition, exposure to the risk source may be taken into QRA estimates (Rausand and Utne, 2009). QRAs are based on a reflective model of risk. In such a model, the parameters included into the measurement need not by necessity belong to an underlying construct to be part of the estimate of the “objective” risk level. Thus, QRAs may consist of parameters that are not necessarily related to one another. Contrary to what is the case in QRAs, risk perception is in the psychometric paradigm believed to be a formative construct. This makes PCA and confirmatory factor analysis (CFA) relevant for examining the dimensional structure of perceived risk. Rundmo and Nordfjrn (2017) carried out structural equation modeling (SEM) aimed at testing the dimensional structure of perceived risk in transport. A formative theoretical model showed a bad fit to the data. Entering worry and concern into such a formative model in addition to probability assessment and judgment of consequences, did not improve the fit of the model.

There is no empirical evidence in transport safety research showing that perceived risk is a formative construct. A theoretical model hypothesizing assessment of probability and judgement of severity of consequences to be independent factors was shown to be satisfactory fitted to the data. Subjective probability assessment and judgments of severity of consequences may be independent factors not belonging to any overall psychological concept forming the judgement, that is, where the judgement “reflects” the overall construct “risk perception.” Rundmo and Nordfjrn (2017) showed, however, that probability and consequence evaluations were significantly associated in lay people’s subjective judgements of transport risk. When probability assessment was added as an exogenous variable, it explained a moderate, however significant, percentage of the variance in judgement of severity of consequences. This was the case in judgement of public as well as private travel modes. Consequently, it may be proposed that the subjective probability assessment may be formative for judgements of severity of consequences. The higher the probability was assessed to be, the larger was also the consequences believed to be if an event with negative consequences should take place, and vice versa.

Associations Between Risk Perception and Driving Behavior

One of the main safety challenges in transport is present in the road traffic sector. A substantial amount of accidents in this sector is caused by risky driving behavior, such as speeding and rule violations. Aligned with the definition outlined in the previous section, traffic risk perception is the subjective interpretation of probability and potential severity of consequences regarding road traffic

accidents. Traffic risk perception is mainly of interest because it may be an antecedent of driving behavior (Machin and Sankey, 2008), such that high perceived risk could be associated with a lower probability of conducting a risk activity and low perceived risk could be associated with higher risk-taking propensity. This assumption aligns with theories that incorporate risk perception to predict risk or health behaviors, such as the Health Belief Model (Janz and Becker, 1984) and Protection Motivation Theory (Rogers, 1983). The state of the art reflects discrepant findings regarding the association between risk perception and driving behavior. For instance, some studies have shown that high traffic risk perception may be associated with less speeding and other rule violations (e.g., Machin and Sankey, 2008; Steinbakk et al., 2019; Ulleberg and Rundmo, 2003) as well as cell phone use while driving (Oviedo-Trespalacios et al., 2017). Common for these studies is that they incorporated affective components of risk into the operationalization of traffic risk perception, or did not accommodate both probability and consequence assessments into the measurement instrument.

There are several studies that call into question the association between risk perception and driving behavior. Rundmo and Iversen (2004) found that perceptions of traffic risk related weakly to self-reported driving behavior. These findings have been replicated in a series of cross-cultural studies conducted in several countries spanning across Europe, Asia and Sub-Saharan Africa, where risk perception either was found to have a modest (e.g., Simsekoglu et al., 2013) or weak association with driving behavior (e.g., Lund and Rundmo, 2009; Nordfjrn et al., 2011). Although Ulleberg and Rundmo (2003) detected a significant correlation between high risk perception and less risk-taking driving behavior, the role of risk perception vanished when attitudes and personality traits were accommodated with traffic risk perception in a structural equation model. Further, Ivers et al. (2009) found no substantial associations between driving behavior and risk perception. The association between risk perception and driving behavior has also been indirectly questioned in cross-country studies. Nordfjrn and Rundmo (2009) found that Norwegians (where driving behavior tend to be safe) reported substantially lower traffic risk perception than individuals from Ghana (where driving behavior tend to be rather unsafe). Given that high risk perception is an antecedent of safe driving behavior, one may have expected the opposite tendency to occur. Similar tendencies were also noted in an earlier study (Hayakawa et al., 2000) where Japanese respondents reported higher traffic accident probabilities than individuals from the United States, despite that road traffic fatality rates are higher in the latter country. A potential explanation is that people habituate and desensitize to the specific hazards and risks present in their own specific traffic environments. This assumption has received support in recent studies using the hazard perception paradigm (Bazilinskyy et al., 2020; Ventsislavova et al., 2019).

Research also indicates that traffic risk perception is associated with demographic characteristics. Empirical evidence for these relations was found in a study where drivers from various age groups rated the accident risk of 100 slide-projected traffic situations (Tränkle et al., 1990; see also Sivak et al., 1989). The results suggested that young males reported less risk than older male drivers, whereas the age effect was not present among females. Research also supports that males tend to underestimate their personal risk when driving and overestimate their driving competence compared with other demographic groups (Glendon et al., 1996). The gender effect in risk perception also seems to be present in other transport domains, such as bicycling (Prati et al., 2019). Deery (1999) showed that young drivers tend to underestimate accident risk across different hazard situations, and that they have higher risk tolerance than more experienced drivers. The research points to the fact that risk perception is subject to demographic variation, and may be an explanatory factor for demographic differences in traffic safety.

Relations Between Risk Perception and Demand for Risk Mitigation in Transport

The previous section discussed how traffic risk perception relates to risky behavior specifically within the road traffic sector. The current section expands the focus to the general surface transport system, and to transport risk mitigating demands exerted upon policymakers and experts by the general public. The association between risk perception and demand for risk mitigation is mainly interesting because it may affect mode use. If people have high risk perception and demand for risk mitigation regarding a certain sector of the transport system (e.g., public transport), and the demand is not addressed by appropriate countermeasures, people may change to other modes (e.g., car) that they perceive to be safer (Phun et al., 2018). Demand for risk mitigation may be more relevant for those who mainly use the public transport sector, as Nordfjrn and Rundmo (2018) reported that such demands were more strongly related to intentions of using public transport than demands for risk mitigation in the road traffic sector.

One of the core challenges regarding demand for transport risk mitigation is that the general public and experts tend to diverge in their perceptions of risk. Studies have reported that experts tend to focus on the probability component of risk perception, whereas the general public stresses the consequence component (e.g., Rundmo and Moen, 2006). The same study suggested that this could be due to that the consequence component is more strongly associated with affect, such as worry, whereas the probability component is more strongly related to cognition and a more analytical approach to risk. Overall, Rundmo and Moen (2006) demonstrated that probability assessments were of minor importance in demand for risk mitigation and that the severity of consequences primarily was significant because they were associated with anticipatory worry, which was a significant predictor variable of demand for risk mitigation. One could expect that experts tend to rely more on cognitive evaluations than the general public which may rely more strongly on affective heuristics to a risk source. In accordance with this assumption, Sjøberg (1999) reported that the expected severity of consequences of a risk source was associated with demand for risk mitigation, whereas probability estimates and such demands were weakly associated in a general public. Contradictory to previous research, Rundmo and Nordfjrn (2013) concluded that risk perception did not predict demand for risk mitigation. Risk perception was, however, found to predict worry which in turn was a significant predictor of demand for risk mitigation (see also Baron et al., 2000). Further, the researchers reported that worry has

an indirect effect on demand for risk mitigation through priority of safety. Similar relations have been demonstrated more recently as [Rundmo and Nordfjrn \(2017\)](#) showed that probability assessments of accidents were not related to demand for risk mitigation in transport, while judgement of severity of consequences directly as well as indirectly was associated with anticipatory worry. In addition to judgement of severity of consequences, worry was a significant predictor of demand for risk mitigation. It seems like that a high demand for risk mitigation is likely when the risk is perceived as high, and the tolerance is low. The higher a risk is perceived and the more worry it induces, the less risk tolerance is expected.

The risk as feelings framework (see section "What is Transport Risk Perception") has been utilized to investigate demand for risk mitigation in transport. [Moen \(2008\)](#) found that both the consequence and probability components related to perceived risk, while the consequence component was a somewhat stronger predictor of feelings than probability estimates. Of note, feelings had a stronger relation to priority of safety than risk perception. Priority of safety was in turn a strong predictor of demand for risk mitigation. This research suggests that risk perception is not all that important for demand for risk mitigation, at least not directly, but risk perception may still be relevant as this construct has mediated effects on demand for risk mitigation by its relation to affect. Several previous studies tended to take for granted that the larger the risk is, the more people would like it to be mitigated. [Rottenstreich and Hsee \(2001\)](#) refuted this assumption, and found that when an outcome has emotional implications, people tended to be insensitive to variations in probability. As such the relative importance of probability depends on the outcome, and the role of probability assessment may be negligible when the outcomes are vivid compared with pallid outcomes.

Risk Perception and Sustainable Transport Mode Use in Urban Areas

General Mode Use in Urban Areas

In addition to being a predictor of driving behavior and safety cognitions such as demand for risk mitigation, risk perception may also be relevant for general mode use in the urban public. People in urban areas usually have several surface transport modes available, such as metro, tram, cars, bicycling and walking. Risk perception may influence the decision-making process between these alternatives. In addition to evaluations of probability and severity of consequences of transport accidents and injuries, transport risk perception includes subjective evaluations of probability and severity of consequences related to security matters. Security is especially viable in public transport and covers the risk of being subject to, for example, physical assaults, theft, and terrorism ([Nordfjrn and Rundmo, 2018](#); [Rundmo and Nordfjrn, 2019](#)). Security is not equally important to traffic safety by use of private motorized travel modes, such as car, motorbike, moped and scooter. Meanwhile, both safety and security are relevant for behavior among cyclists and pedestrians ([Kummeneje and Rundmo, 2019, 2020](#); [Kummeneje et al., 2019](#)).

[Rundmo et al. \(2011\)](#) investigated a number of risk judgements in relation to urban mode use. Opposing previous studies which showed that the consequence component is more important for risk decisions, the findings showed that the probability component was more important for mode use than the consequence component. Those who used public transport more often perceived the probability of an accident to be less compared to the two groups of respondents who used private modes more often than public modes. Accident probabilities were also rated to be overall higher for private modes compared to public modes. [Roche-Cerasi et al. \(2013\)](#) reported that respondents who mainly used public transport in urban travel assessed higher probability of experiencing criminality, such as violence, in public transport than those who mainly used private modes, such as car. Those who used private modes were generally more worried about accidents, whereas those who used public transport were more focused on security issues such as criminality and terrorism. These findings align with other studies (e.g., [Backer-Grondahl et al., 2009](#)) which showed that people worry more about accidents than unpleasant incidents on private modes, while they worry more about unpleasant incidents than accidents on public modes. However, challenging the findings of previous studies the results reflected rather negligible associations between mode use and risk perception.

Some studies have also revealed indications of avoidance behavior due to risk perception. For instance, [Nordfjrn et al. \(2014\)](#) found that high risk perception of terrorism and major accidents as well as risk perception related to theft and violence predicted more car use among Norwegian commuters. These findings are opposed by [Elias and Shiftan \(2012\)](#) who concluded that risk perception had a weak relation with the intention to use public transport and that people focus on other priorities, such as advantages of using car, rather than health risks when choosing to use a car. [Nordfjrn and Rundmo \(2018\)](#) found that individuals who had experienced a negative security incident on public transport in recent years had elevated risk perception and worry across public and private transport modes. The findings further reflected that high risk perception in public transport predicted a lower intention of using public transport modes, whereas high risk perception in private motorized transport predicted a stronger intention to use public modes. For transport risks where consequences are perceived to be low, for example, for cyclists and for being a pedestrian during daytime and in spring and summer, probability assessments have been found to have a direct association with how often people cycled and walked during winter and summer ([Kummeneje and Rundmo, 2019, 2020](#)).

Active Mode Use in Urban Areas

Active mode use, such as walking and cycling, is given high priority in European transport policy. The use of active modes is seen as a pro-environmental as well as a health promoting behavior. Several previous studies have examined risk perception and worry in relation to active travel. For instance, [Moen and Rundmo \(2006\)](#) and [Oltedal and Rundmo \(2007\)](#) found that the respondents were less worried about being in an accident when cycling and walking compared with using other private travel modes. The respondents

also perceived the probability of being in an accident as the lowest as a pedestrian and cyclist compared with other private transport modes (car, motorcycle, scooter). Another interesting finding was that the respondents reported that the consequences of being in an accident were greater when walking than when cycling, but still lower than when using motorized transport modes.

According to [Chaurand and Delhomme \(2013\)](#), the study of risk perception related to cycling has received relatively little attention. The same is true for pedestrians, and few studies to date have focused on cyclists' and pedestrians' perceived risk and worry. Much of the research in this field has been conducted to aid engineers and city planners in designing and improving the road infrastructure. In most of these studies the respondents have been asked to rate their overall risk perception of a route described by video-clips, simulations, pictures, or surveys. In these studies, the perceptions of risk and feelings related to the road infrastructure or traffic environment have been in focus (e.g., [Lawson et al., 2013](#); [Llorca et al., 2017](#); [Manton et al., 2016](#); [Moller and Hels, 2008](#); [Rankavat and Tiwari, 2016](#)). The findings are difficult to compare across these studies due to inconsistent operational definitions and measures of risk perception.

In recent studies, risk perception of active modes has been operationalized by measuring both the respondents' assessment of probability and judgment of the severity of consequences of different types of hazards when cycling or walking ([Kummeneje and Rundmo, 2018, 2019, 2020](#); [Kummeneje et al., 2019](#)). [Kummeneje and Rundmo \(2018\)](#) and [Kummeneje et al. \(2019\)](#) found seasonal differences in cyclists perceived risk and worry about being in an accident. The cyclists perceived the risk to be higher and were more worried when cycling in winter conditions compared with summer conditions. Risk perception and worry were further found to be important predictors of both the decision to cycle and the frequency of cycling during wintertime. In a study of pedestrians' risk perception and worry, [Kummeneje and Rundmo \(2019\)](#) found a strong association between risk perception and worry among pedestrians. Further, they found that worry was moderately associated with walking frequency during night-time, and how often individuals walked alone outdoors during night-time. These associations were stronger for people without access to a private car. No associations were found between worry and walking frequency during the daytime. In a different study, [Kummeneje and Rundmo \(2020\)](#) found that risk perception and worry not only were important for travel behavior, but also for risk-taking behavior and conflicts with other road users when cycling.

Risk Perception and Mode Use on School Trips

Risk perception could also play a role when people make transport mode choices on behalf of others, such as for school children. Among school-aged children (6–17 years), it is evident that pupils younger than 12 years are less likely to accurately perceive traffic risks ([Van Goeverden and De Boer, 2013](#)). Due to this fact, parents are more likely to make decisions regarding their children's travel mode in trips to/from school ([D' Haese et al., 2011](#); [Mehdizadeh et al., 2017a](#)). In addition to contextual variables, such as distance from home to school and parental socioeconomic characteristics, perceived risk about available transport options may have a pivotal role in mode choice decisions in school trips. For instance, due to a higher perceived risk regarding the walking/cycling route to school, parents may prefer not to let their children walk/cycle to school, even when the school is located close to their residential location. Consequently, it can be concluded that different aspects of risk perception concerning various travel modes can impact on mobility styles and transport mode choices. Higher perceived risk regarding active and public transport modes may lead to more use of motorized transport. Such reasoning is in line with psychological theories, such as the Protection Motivation Theory ([Rogers and Prentice-Dunn, 1997](#)) and the Health Belief Model ([Rosenstock, 1974](#)).

Although there is much research on mode choice behavior in school trips, less attention has been devoted to the investigation of risk perception in school trips. [Mehdizadeh et al. \(2017b\)](#) analyzed the relative roles of parental risk perceptions and worry toward different transport options on pupils' mode use in the Middle East context. Both major cognitive components of risk perception, that is, the probability and consequence estimates of accident involvement, were significantly associated with using active modes instead of motorized modes. It was also concluded that worry could impact on parental mode choice decisions. The authors showed that parents who had high risk perception and more worry about walking, were more likely to choose motorized modes for their children in school trips. In a similar way, after controlling for the effects of child's gender and distance from home to school, [Fallah Zavareh et al. \(2020\)](#) found that parental worry was significantly higher in the group of non-walking pupils than the group of walking pupils. In another study [Mehdizadeh et al. \(2018\)](#) showed that parents worried the most about letting pupils walk alone to school compared to other modes of transport.

Although very few studies focused on the role of risk perception on school trips, several studies of parental worry about children as pedestrians have been conducted ([Mammen et al., 2012](#); [Peterson et al., 1990](#); [Salmon et al., 2007](#)). [Mammen et al. \(2012\)](#) investigated differences in parental worry about children's school travel. They found that parents who escorted their children to school worried more than other parents about the possibility of strangers and bullies approaching their child and about the traffic volume around the school. [Salmon et al. \(2007\)](#) reported an association between the child's use of active transport to school and parents' concern that their child may be injured in a road accident. [Peterson et al. \(1990\)](#) investigated parents' feelings of worry about different types of injury, including their children being injured by a motor vehicle when walking. Overall, the results showed that parents reported low feelings of worry about injuries.

Parental risk perception can also influence willingness to accept interventions designed to change travel behavior on school trips. In one of the few studies that focused on this, [Fallah Zavareh et al. \(2020\)](#) reported that more parental worry was associated with a weaker intention to let non-walking pupils walk in the presence of a proposed IT solution which informed parents about children's entrance to and exit from the school. Parental worry had no significant association for the group of walking pupils. Predictors of parental risk perception in relation to children's commuting to school have been subject of a few previous studies. [Nevelsteen et al.](#)

(2012) investigated the relationship between perceived traffic safety of parents and found that parental safety perception can be explained by the age and gender of the child as well as traffic infrastructure near home or destinations frequently visited. Lam (2001) reported that the age of the child, gender of the parent, employment of the parent, living environment, and previous injury experience were significantly associated with parental risk perception of children's road safety.

In addition to socio-demographic and situational predictors, risk perception may be influenced by individual competence (Slovic, 2007). For instance, Rudner (2012) found that the interaction of parental conceptions regarding the environment and their evaluations of the children's competencies (risk control, skill in dealing with the risk and their knowledge about potential hazards) influence how parents perceive risk, which in turn may affect parental decisions for children's independent mobility. Studying a group of non-walking pupils, Fallah Zavareh et al. (2020) also showed that positive attitudes toward safety responsibilities in transport, and trust in experts' knowledge were significantly associated with parental worry about children's risk of being involved in a road crash when walking to school.

Summary and Conclusions

The state of the art suggests that risk perception is relevant for driving behavior, demand for risk mitigation and urban transport mode use. However, several studies did not operationalize risk perception in line with risk theory, but incorporated affective components, such as worry, into the risk perception construct. It might be valid to include operationalizations of affect as well as other risk judgements (e.g., risk tolerance, priorities of safety, risk aversion etc.) into the prediction models when examining the role of risk perception for transport behavior. Future studies could benefit by a more restricted and clear-cut operationalization of traffic risk perception as perceived probability and consequences of accidents. Affect and other related risk judgements could be incorporated as separate constructs predicting the outcome variables. This would facilitate comparison of findings across studies as well as risk perception research which is more aligned with psychological risk theory.

Glossary

Symbolic aspects of cars the extent to which a car is seen as or used as a symbol of a person's unique characteristics or group membership (including broad social categories such as socio-economic status).

Brand-image congruency the extent to which (perceived) characteristics of a car brand reflect the personality characteristics of the car owner.

Costly-signals of status the extent to which expensive cars are seen and used as symbols (or costly signals) of status and wealth.

Personal and social identity the ways in which people describe themselves and others reflecting their unique characteristics and group membership.

Affective aspects of cars any emotional aspects associated with buying, owning and driving a car such as stress, pleasure, thrill, relaxation as well as social emotions such as pride.

Car pride the self-conscious emotion derived from the appraisal of owning and using cars as a positive self-representation.

Introduction

People buy and drive cars for many reasons. Instrumental reasons, such as flexibility, cost, and speed are important, but other factors, such as status, prestige, pride, and driving pleasure also play a significant role in understanding car ownership and use. The idea that cars have symbolic and affective value that is (related to but) distinct from their instrumental value is well understood by the car industry and has been discussed in academic and non-academic literature for several years (Birdwell, 1968; Diekstra and Kroon, 2003; Evans, 1959; Flink, 1975; Gossling, 2017; Marsh and Collett 1986; Stokes and Hallett, 1992).

The aim of this chapter is to provide an overview of this literature. It will start with defining concepts, outlining theory and discussing research evidence. The chapter will look ahead to review how these factors help explain car use, and responses to travel demand management strategies. It will end with an exploration of the role of these factors for future developments in car technology, looking at electric vehicles and autonomous driving.

Symbolic Aspects of the Car and Identity

Symbolic aspects are associated with the extent to which a car is seen as or used as a symbol of a person's unique characteristics or group membership (including broad social categories such as socio-economic status). The symbolic value of cars is strongly related to social identity theory. Within psychological literature it is well known that people use symbols to relate to each other and the world at large (Dittmar, 2007). Material symbols help people make sense of their social world. Highly visible possessions such as cars enable people to make important quick social judgments about others (their values, intentions, beliefs, status, etc.), especially when more detailed information is not available (e.g., in brief interactions with new people). They also enable people (more or less intentionally) to manage the impressions they make on others. Visual material objects such as the car are extremely useful in these processes of impression formation, and impression management (Schlenker, 1982).

Three interrelated types of symbolic function of cars can be distinguished (Dittmar, 2007). First, cars can be categorical symbols, or signs of a social identity that people can use to express their social standing, wealth, and status and/or to signify group membership. Second, cars can signify special relationships with specific individuals. Finally, cars can have self-expressive function. They can symbolize the owner's personal identity, representing their values, personalities, attitudes, and unique qualities.

The first and latter of these topics have been studied extensively, as will be shown below. The second has received less attention. However, material objects such as gifts or heirlooms have been shown to be prominent symbols of special relationships (Dittmar, 2007). Cars can also fulfil such symbolic function as is demonstrated by this quote from one of the participants of Fraine et al. (2007):

My dad gave it [her car] to me for my 18th birthday and even though I should get rid of it because it's causing me a lot of mechanical problems, I don't want to get rid of it because of that sentimental value [young female] Fraine et al., 2007, p 208.

Many people will have special memories of others associated with their car ownership and use. The car plays an important function in developing and maintaining social relationships with important others—to visit friends, join clubs or ferry the children around (Murtagh et al., 2012).

The symbolic value of cars has been identified through different research methods. Qualitative studies have found that people talk about cars as symbols of prestige (as a symbol of wealth), having an exciting life, masculinity, and being a valued member of society (Hiscock et al., 2002). Experimental studies have demonstrated that people respond differently to others when they are seen with a high or low status car (Dun and Searle, 2010). In self-report surveys, people rate the symbolic value of cars higher than that of other transport modes (Steg, 2005).

Brand Image and the Self; Personality and Self-Congruency Theory

Cars are ideal visual material symbols. They are cultural symbols that reflect socially shared stereotypes of groups of people. One can design an easy (and perhaps fun) matching game with images of cars (e.g., a pink VW Beetle, a blue Peugeot, and a black Mercedes) and characteristics of people (gender, income, job type, personality, etc.). Car advertisers label cars with personality characteristics. Websites publish quizzes to tell people “what your car says about you”. For instance, “Owning a cherry red sports car means you take financial risks”; “Driving a Ford means you're friendly but direct”; “BMW drivers consider themselves knowledgeable”; “SUV drivers are pedantic about safety”; and “Driving a Toyota means you play it safe” (www.hotcars.com).

The personality of cars and people have been studied for quite a few years. In 1959, Evans studied the perceived personalities characteristics of two common cars (Ford and Chevrolet) and their owners to examine whether people drive cars that match their personality. Birdwell (1968) found significant congruence among the perceived personality characteristics of car owners and their cars. This was particularly so for higher priced cars. Many more studies since then have demonstrated that this self-image congruency can explain car brand preferences (Kressmann et al., 2006), car purchase intentions (Ericksen, 1996), and satisfaction with a purchased car (Jamal and Al-Marri, 2007). Such effects have been found for people's perceptions of their actual as well as their ideal self (who they would like to be; Lönnqvist et al., 2019). Self-image congruency theory (Sirgy, 1982, 1986) suggests that consumer choices are influenced by the extent to which consumers perceive a product's image to be consistent with their self-image. Clearly people are drawn towards cars that reflect how they (wish to) see themselves.

Cars as Symbols of Success, Status, and Wealth

Veblen coined the term conspicuous consumption in 1899 to describe how discretionary income was used by the middle classes to display their status and prestige. Spending a lot of money on things you do not need is the ultimate symbol (or costly signal) of status and wealth. Cars are expensive, making them excellent “costly signals” of status and wealth.

The status value of cars has been shown to influence social perceptions. Dunn and Searle (2010) demonstrated that the same male model was perceived as more attractive by women when presented with a ‘high status’ (Silver Bentley Continental GT) rather than a ‘neutral status’ car (Red Ford Fiesta ST). Men were not influenced by this status manipulation. Attractiveness ratings were also studied by Sundie et al. (2011) who demonstrated that a display of status specifically enhances short-term sexual attraction. Men presented with a high status (Porsche) rather than a low status car (Honda) were rated as more desirable for short-term sexual relationships. They were also rated more open to such short-term sexual relationships (Sundie et al., 2011). The status value of the car also affects how men rate each other. Hennighausen et al. (2016) showed that men with luxury cars were rated more attractive, intelligent and ambitious by other men, but they were also more likely seen as a rival, competitor, and mate poacher. These studies suggest that the flaunting a high-status car may communicate to others a very specific type of attractiveness; as someone to have fun with, but not to establish long-term relationships or friendships with.

Car status is related to anger and aggression on the road (Galovski and Blanchard, 2004). Doob and Gross (1968) demonstrated that when a road is blocked by a high-status car 50% of frustrated drivers result into horn honking whereas 84% of frustrated drivers honked when the road was blocked by a low status car. These findings were repeated in more recent work which showed that when a high-status car loiters in front of a traffic light it results in less aggressive responses (honking) from others in comparison to a low status car (McGarva and Steiner, 2000). McGarva and Steiner (2000) also found that drivers of high-status cars are more likely to respond aggressively. When car status of aggressor and frustrater are examined together status similarity appears to result into less aggression.

High-status cars not only change the way people see others they also affect the way we see ourselves and can support a positive sense of self. [Sivanathan and Pettit \(2010\)](#) demonstrated that when people were asked to imagine owning a high-status car (rather than low status) they coped better with negative feedback. Moreover, people with low self-esteem were willing to pay more for a high-status car and low self-esteem helped explain why lower income participants were willing to spend more money on a high-status car. Based on four studies they suggest that participants use status consumption to help restore self-integrity, boost self-esteem, and “restore psychological pain” ([Sivanathan and Pettit, 2010](#)).

Of course there are individual differences. Some people attach more importance to owning the right type of car than others. Male drivers tend to value symbolic and affective outcomes more than female drivers ([Steg et al., 2001](#)). Conspicuous consumption has been shown to be higher among lower income groups who spent a greater proportion of their income on buying luxury status products ([Landis and Gladstone, 2017](#); [Sivanathan and Pettit, 2010](#)). Moreover, people with a stronger materialistic value orientation (who believe that acquiring wealth and material possessions will improve their wellbeing and status; [Richins, 2004](#)) are more likely to want to drive an expensive car for a day, believe this would make them feel powerful and that others would be impressed ([Gatersleben, 2011](#)). Flaunting a high-status car has also been shown to be linked personality. People (particularly men) who score higher on narcissism and disagreeableness are more likely to drive high-status cars ([Lönqvist et al., 2019](#)).

Autonomy, Territoriality, and Attachment

Over time people can develop strong bonds with their car and car ownership and use can become an important part of people’s sense of self ([Goodwin, 1997](#); [Mann and Abraham, 2006](#); [Steg, 2005](#)). Belk (1991) refers to Sartre (1943) who suggested that there are three ways in which possessions may become part of the self: through mastery and control of the object, by creating an object, and through getting to know the object. Following this logic the car can become part of people’s sense of self when they learn to drive and master the object, through ownership and personalization, and through use and experience.

[Fraine et al. \(2007\)](#) examined car attachment through the lens of territoriality theory and demonstrated that for some people the car can become an important primary territory, which is reflected in the way they refer to their car as important to their sense of self, as well as their use of territorial marking (personalizing the car) and behavioral responses to territorial invasion. Higher car attachment was associated with stronger negative reactions to territorial invasion: tailgating. Others have also shown that those who identify more strongly with their car are more likely to find it annoying if someone were to touch their car, write in dust on their car, change settings on the dashboard or park too close ([Watts, 2008](#)).

Possessions are psychologically important to people when they provide control and a sense of mastery ([Dittmar, 2007](#); [Furby, 1978](#)). Owning and driving a car can provide a sense of control over people’s social and physical world that goes well beyond what a human being can achieve without the car. This is something that no other mode of transport can provide in the same way ([Diekstra and Kroon, 2003](#); [Flink, 1975](#); [Goodwin, 1995](#); [Marsh and Collett, 1986](#)). Autonomy and related aspects such as a sense of control, independence and freedom are often rated by people as the key advantage of cars ([Hiscock et al., 2002](#); [Lupton, 2002](#); [Mann and Abraham, 2006](#); [Steg, 2003](#); [Stradling et al., 1999](#)). The convenience provided by cars gives people a sense of control over their lives ([Hiscock et al., 2002](#)), whereas the ‘unreliability [of public transport] does the opposite’ ([Hiscock et al., 2002](#)).

Autonomy related to a car is twofold ([Jensen, 1999](#)): (1) freedom from others (privacy) and (2) freedom from time schedules ([Hiscock et al., 2002](#); [Lupton, 2002](#); [Mann and Abraham, 2006](#)). The first is linked to Fraine’s perspective of the car as a primary territory. Autonomy has a strong instrumental basis; for instance, being able to close the car door to control privacy or having the option to choose travel time and route (e.g., [Hiscock et al., 2002](#); [Lupton, 2002](#); [Mann and Abraham, 2006](#); [Steg, 2003](#); [Stradling et al., 1999](#)). The sense of control and mastery that car ownership and use brings plays an important role in explaining car attachment (Belk, 1991).

Affect

Affective aspects refer to the any emotional aspects associated with buying, owning and driving a car such as pleasure, thrill, relaxation as well as social emotions such as pride. Affective aspects can refer to both negative and positive emotional experiences such as feeling stressed, excited, pleasant, or bored. It is well known that driving (to work) can be stressful ([Wener and Evans, 2011](#)). However, car commuter journeys are more likely to evoke feelings of relaxation, freedom, and control ([Gatersleben and Uzzell, 2007](#)), especially when compared to public transport (e.g. [Jensen, 1999](#)). For many people the car is a place to relax and unwind after a day of work (e.g., [Steg et al., 2001](#); [Gatersleben and Uzzell, 2007](#); [Mann and Abraham, 2006](#)). As one of Lupton’s (2002) respondents noted: ‘it’s a release sometimes . . . get onto the road . . . and chill out’ (p. 280).

Positive affective experiences of car use are associated with the two autonomy functions of the car: freedom from others and from timetables, as is nicely demonstrated by these two quotes from [Fraine et al. \(2007\)](#):

“I feel relaxed when I sit in my car. Sometimes, if I’m not going for a drive, I’ll just go sit in it and put on the radio. And in a way I’m in my element a little bit yeah. No distractions” [young male] [Fraine et al., 2007](#), p 208. Yeah for me it’s a link to the outside world. It’s freedom. I can remember there’s one time where I didn’t have access to it and you really feel trapped [adult male] [Fraine et al., 2007](#) p 208

Positive affective experiences of driving have been linked to symbolic aspects. [Zhao and Zhao \(2015\)](#) coined the term car pride defined as the self-conscious emotion derived from the appraisal of owning and using cars as a positive self-representation. Car pride captures symbolic aspects such as the degree to which people believe owning and driving a car provides prestige and distinction (classy car, distinguish you from ... give you prestige), and affective aspects related to car attachment (I'm fond of my car), driving pleasure (exciting, pleasure) and autonomy (control). The link between symbolic and affective aspects is also made by others. [Bergstad et al. \(2011\)](#), for instance, found an empirical distinction between affective-symbolic aspects (kick out of driving, prestige, sense of power, pleasure, etc) and instrumental-independence aspects (flexibility and control go where you want), but not between affective and symbolic aspects.

Explaining Car Use and Willingness to Change

The perceived instrumental, symbolic and affective benefits (and costs) of the car predict car ownership and use ([Steg et al., 2001, 2005](#)). Moreover, the car is rated more positively than other modes on almost all aspects ([Steg, 2003](#)). Many other studies have confirmed these findings demonstrating that car ownership and use for a range of different purposes (leisure, work) is associated with these perceived benefits ([Anable and Gatersleben, 2005; Bergstad et al., 2011; Bălău, 2019; Ingeborgrud and Ryghaug, 2019; Van Tan and Fujii, 2008](#)).

Psychological attachment to the car has also been linked to levels of car use ([Fraine et al., 2007](#)) and people who are emotionally attached to their car tend to drive more compared to those who are less emotionally attached ([Nilsson and Küller, 2000](#)). Car attachment is also linked to greater resistance to any proposed changes to car ownership and use ([Goodwin, 1995; Sheller, 2004](#)). The more car drivers derive a sense of personal identity from driving, the less willing they are to reduce their car use ([Stradling et al., 1999](#)). People who feel more psychologically attached to their car express greater reluctance to accept a range of travel demand management strategies ([Nilsson and Küller, 2000](#)) and a reduced willingness to accept car sharing schemes ([Paundra et al., 2017](#)). The extent to which travel demand measures are perceived to threaten people's identities (as a good parent, as a car user) has been shown to predict resistance to accept these measures and change behavior ([Murtagh et al., 2012](#)).

Electric Vehicles

Although psychological attachment to cars may be associated with lower willingness to reduce car use or accept measures that curtail car use, this may not necessarily be the same for people's willingness to adopt new car technologies ([Griskevicius et al., 2010; Ingeborgrud and Ryghaug, 2019; Schuitema et al., 2013](#)). The symbolic value of these cars has been shown to be positively related to willingness to adopt these new technologies.

Experimental studies found that participants were more likely to choose a hybrid car rather than a standard luxury car when they were more concerned about their status (in an imagined job interview: [Griskevicius et al., 2010](#)). However, these effects were only found when the hybrid car was more expensive. They were also stronger when choices were made in public than in private (a shop or on-line). This work is in line with the ideas of costly signaling and conspicuous consumption suggesting that more sustainable products may be more attractive when they can be used as costly signals of status.

The relatively importance of symbolic aspects for people's willingness to adopt electric vehicles was also shown by [Schuitema et al. \(2013\)](#) who found that both the perceived hedonic (excitement, pleasure) and symbolic (pride, embarrassment) value of electric vehicles (plug in and hybrid) predicted willingness to buy electric cars. [White and Sintov \(2017\)](#) found that intentions to buy and rent electric cars were higher when they were rated higher as symbols of environmentalism and social innovation. As predicted by self-congruency theory people with a strong pro-environmental self-identity were more likely to have positive perceptions of electric vehicle attributes.

Autonomous Cars

A major technological innovation in the car industry is the autonomous car. People's willingness to adopt such cars is strongly associated with safety concerns and trust in the system. [Fraedrich and Lenz \(2016\)](#) asked German drivers to evaluate a range of autonomous driving scenarios (full autonomy, parking, on demand vehicles) and found acceptance very low. Open ended comments on the scenarios suggested that perceived instrumental costs and benefits of autonomous cars were mixed, affective evaluations were overwhelmingly negative and very few comments referred to symbolic aspects. However, symbolic aspects did appear important in a study among 159 UK car owners ([Bird, 2011](#)). Respondents rated a fictitious normal car and a (semi or fully) autonomous version of that car on a range of values, following [Schuitema et al. \(2003\)](#). The autonomous cars were rated significantly lower than the "normal" car on conservatism (safety, security) and hedonism (pleasure, excitement) but significantly higher on status (pride, power, wealth), see [Fig. 1](#).

Figure 1 The perceived status, conservative and hedonic value of “normal” and autonomous cars.

Conclusion

Cars are bought and used for many reasons. This chapter demonstrated that the extent to which cars (are seen to) reflect a person’s unique qualities and group membership (status, personality) affects purchase behavior, driver behavior as well as the social interactions. It also showed that positive symbolic and affective experiences influence car use, driver behavior, as well as people’s willingness to change their behavior, accept travel demand measures and adopt new car technologies.

Cars are clearly more than instrumental objects that get us from A to B, although the instrumental aspects of the car are intricately linked to the symbolic and affective aspects. Changes in the material aspects of cars and the social contexts are likely to change those symbolic and affective aspects. For instance, a high-status car will lose its symbolic status value when it is owned by many, technological advances will change perceptions of what is new or exciting and changes in costs will alter its value as a costly signal.

Overall though symbolic and affective aspects of car ownership are important, in understanding why and how people buy and use cars, how they relate to each other and in helping us to understand, predict and plan future demand use management and technological innovations.

Introduction

In traffic psychology, researchers typically conduct an experiment, the data of which are subsequently analyzed. For example, a researcher may conduct a driving simulator experiment with different time-budget conditions to evaluate how drivers reclaim control from an SAE Level 3 automated vehicle. For each driver and time-budget condition, scores on measures are obtained, such as the maximum absolute steering wheel angle, self-reported criticality of the situation, and take-over time. In other cases, the traffic psychologist may investigate individual differences, for example, by analyzing accident records or data obtained from Internet-based questionnaires.

The available experimental data are invariably subjected to statistical tests. We analyzed the papers of 129 experiments on automation-to-manual take-overs (list of papers available in a meta-analysis by [Zhang et al., 2019](#)) and found that *P*-values were used in as much as 95% of the 129 studies. ANOVAs (65% of studies), usually combined with post hoc (Bonferroni-corrected) *t*-tests, as well as paired/unpaired *t*-test presented separately (46% of studies), were among the most common statistical procedures. Nonparametric test variants (e.g., Wilcoxon test) were common as well. In areas of traffic psychology that are concerned with individual differences, on the other hand, correlation coefficients and data reduction techniques, such as exploratory factor analysis, are typically used ([Fig. 1](#)).

When we were asked to contribute an article about statistics in traffic psychology, we realized that there are already many articles and books that detail how statistical tests should be conducted, sometimes accompanied by an extensive step-by-step plan tailored to a specific software package (e.g., [Field, 2013](#)). It does not appear scientifically valuable to repeat such information. What appears valuable, however, is to report on common pitfalls and misconceptions regarding statistics in the field of traffic psychology.

This article was written based on the first author's subjective experiences as a researcher and peer reviewer in the field. The pitfalls were selected based on estimates of risk, where risk is a function of how often these pitfalls occur and how severe their consequences are. There are, of course, many other pitfalls of statistical methods, but the list below is regarded to be of direct relevance to the traffic psychology researcher.

The *P*-Value is Not the Same as the Probability That the Null Hypothesis is True

In a large proportion of papers in traffic psychology, statistical tests are performed. These tests yield *P*-values, based on which statements are made about hypotheses. Formally, the *P*-value indicates how extreme one's observations are under the assumption of a null hypothesis. A critical thing that tends to be overlooked in null-hypothesis significance testing is that *P*-values do not allow for making direct claims about whether the null hypothesis is true or false.

A thought experiment can prove the point. Suppose one investigates psychic abilities, such as whether participants can predict the outcome of a random number generator (see [Bem, 2011](#)). This hypothesis is certainly intriguing and spectacular if true. However, it is impossible to be correct, given the current knowledge of physics, and the fact that, as far as we know, no person in the world can systematically outplay the roulette table at casinos. Any significant *P*-value ($P < 0.05$) must therefore be a false positive (see [Wagenmakers et al., 2011](#) for a similar argumentation).

The above message is illustrated in [Fig. 2](#). Let us assume that, in a given subfield of traffic psychology, as much as 95% of the hypotheses are false. That is, there is only a 5% probability that the effect one hopes to find exists in reality. In such a case, even if assuming a large sample size and corresponding statistical power of 80%, then still only 46% of the statistically significant effects reflect a true effect. In other words, it is more likely that a significant effect ($P < 0.05$) is a false positive than a true positive.

This type of Bayesian reasoning corresponds to the argumentation of John Ioannidis in his well-known work "Why most published research findings are false" ([Ioannidis, 2005](#)). [Fig. 2](#) provides an example where statistical power is reasonably high

Figure 1 Example (simulated) data for an experiment on automation-to-manual take-overs, with three time-budget conditions. A sample size of 20 per condition was assumed. The blue cross and the number next to each bar indicate the group mean.

Figure 2 Illustration of the effect of the pre-study probability that a research finding is true for statistical power $(1 - \beta) = 80\%$. For a significance level (α) of 5% and a pre-study probability of 5%, only 46% of the detected statistically significant effects are true positives.

(80%). Using the same figure, it can be understood why low statistical power (e.g., small expected effects or small sample sizes) reduces the probability that a research finding is true. For example, if power were 60% instead of 80%, then there would be fewer true positives, and, as a result, only 39% of the positive (i.e., statistically significant) results would be true positives. In other words, low statistical power does reduce not only the probability of detecting an effect but also the likelihood that an observed significant effect is a true effect (Button et al., 2013). Note that the example in Fig. 2 does not even consider the phenomenon of bias, where researchers may unconsciously or consciously distort research findings because researchers generally like to find significant effects (Ware and Munafò, 2015). Bias is discussed in the third section of this article.

In traffic psychology, effects are often well established and replicable, because experimental conditions are clearly operationalized (e.g., human-machine interface conditions, traffic conditions in a driving simulator), and the driver's inputs (e.g., steering

Figure 3 Distribution of P -values (so-called P -curve) when submitting two samples ($n = 20$ each), with Cohen's $d = 0.8$, to an independent-samples t -test. The vertical dashed lines are drawn at $P = 0.04$ and $P = 0.05$, respectively. The bins in this figure are 0.001 wide.

wheel angle, throttle and brake inputs) are easily measurable and causally related to the task conditions. For example, the effect of time budget and take-over request modality on take-over times are known to be strong and reproduced many times (see Zhang et al., 2019, for a meta-analysis). However, in subfields of traffic psychology, researchers may sometimes make rather spectacular, surprising, or intriguing claims. Examples may be the effects of emotional priming, mindfulness, or pleasant smells in the car on driving behavior. While the existence of such effects cannot be ruled out, the underlying mechanisms of how these would affect driving behavior are less clear, and hence the credibility of the findings is low. When these types of findings are obtained via small samples and supported by a barely significant effect (e.g., $P = 0.04$), scepticism is appropriate. Conversely, if an effect is supported by theory or the P -value is small (e.g., $P < 0.001$), then the finding is more likely to be replicable.

Incidentally, it should be noted that P -values below 0.05 are more prevalent in the literature than they should be. It is well established that significant findings ($P < 0.05$) are more likely to appear in papers than nonsignificant findings ($P > 0.05$), a phenomenon known as publication bias. Research also shows that the use of P -values is becoming increasingly common in the abstracts of papers (Chavalarias et al., 2016; De Winter and Dodou, 2015), and there is some evidence for “convenient” downwards rounding of P -values to be able to claim “ $P \leq 0.05$ ” (Hartgerink et al., 2016).

The expected rarity of P -values in the $P = 0.04$ – 0.05 region can be illustrated using a computer simulation. Suppose one wishes to compare the means of two samples. The first sample is drawn from a population with a mean of 0 and a standard deviation of 1; the second sample is drawn from a population with a mean of 0.8 and also a standard deviation of 1. In other words, the true effect size is large (Cohen's $d = 0.8$). If one draws random samples of $n = 20$ each and performs 100,000 independent-samples t -tests, then most P -values will turn out to be very small. In this specific case, only 3.6% of the P -values are between 0.04 and 0.05 (see Fig. 3 for the results of the simulation).

In summary, a P -value slightly below 0.05 does not imply that the alternative hypothesis is true; one should consider the plausibility of the hypothesis (Ioannidis, 2005). Furthermore, if there truly is a strong effect in the population, P -values just below 0.05 are rare, and small P -values (e.g., $P < 0.001$) are more likely.

Possible solutions to the above-mentioned problems are the use of larger sample sizes (Button et al., 2013) and the use of lower alpha values (e.g., 0.005 instead of 0.05; Benjamin et al., 2018; but see Lakens et al., 2018, for counterarguments). Some researchers in traffic psychology have used Bayesian statistics to counteract the problem of making wrong inferences based on null hypothesis significance testing (see Körber et al., 2016 for a study on Bayesian statistics in automation-to-manual take-overs). Although Bayesian statistics are popular in several areas of transportation research, its use in traffic psychology and other human-related fields is still limited (see Chavalarias et al., 2016 for a survey of biomedical papers).

Everything is Correlated

In traffic psychology, researchers sometimes have access to extremely large databases. For example, it has been found in a study of over 10,000 drivers that self-reported violations are predictive of self-reported accidents (Wells et al., 2008) and that demographic variables are predictive of the willingness to use a driverless shuttle (Nordhoff et al., 2018). Similarly, accident statistics of hundreds

of thousands of drivers have revealed interesting relationships between crash involvement, traffic tickets, and individual characteristics (Factor, 2014). For such large sample sizes, however, even extremely small effects are statistically significantly different from 0 (Nunnally, 1960; Standing et al., 1991), an inconvenience which Meehl (1990) referred to as the “crud factor” (p. 108).

The bottom line is that a statistically significant effect does not imply that this effect is important. For example, the correlation between self-reported violations and self-reported accidents is about 0.15 (De Winter et al., 2015), which may be interesting for testing theories about personal predispositions but probably not very useful for identifying accident-prone drivers. Colleague Evans (2009) once explained that, in principle, wearing a second t-shirt contributes to a reduction of road traffic deaths, as this extra layer of clothing has a protective effect in absorbing energy during a crash. However, as he pointed out, this, of course, does not mean that researchers should advise drivers to put on an extra t-shirt before entering their cars.

The above concerns about the meaninglessness of null hypothesis significance testing do not only apply to small effects; they also apply to strong effects, in particular in the context of human performance and behavior. A common phenomenon in the analysis of human performance, including driving, is that performance measures are almost always correlated. For example, a driver who is skilled in lane-keeping will probably also be skilled in car following, and a positive statistically significant correlation coefficient between performance measures (e.g., standard deviation of lateral position and standard deviation of headway) is virtually guaranteed. Horn and McArdle (2007) noted: “practically every variable that in any sense indicates the good things in life—health, money, education, and so forth, and athletic and artistic abilities, as well as cognitive abilities—correlate positively with every other such thing that everything is significantly correlated” (p. 219).

In questionnaire research as well, strong positive correlations between variables are the rule rather than the exception, due to method effects. This problem, which has been vigorously highlighted by a few authors in traffic psychology before (in particular Af Wählberg, 2010, 2017), seems to have fallen on deaf ears in a large portion of researchers.

The problem of methods effects in questionnaire research can be illustrated using a small computer simulation (see also De Winter et al., 2019). First, let us assume two constructs (e.g., driving errors and driving violations), which are uncorrelated in the population. Let us also assume that these constructs can be measured using a five-point Likert scale (e.g., 1 = never, 2 = hardly ever, 3 = occasionally, 4 = quite often, 5 = frequently). The distribution of the correlation coefficients, assuming a sample size of 300 respondents, is shown in Fig. 4 (this distribution is based on 100,000 repetitions) and averages at $r = 0.00$, as expected. Next, one-third of the respondents (100 of 300) are simulated to have a different notion of quantity and the meaning of words such as “occasionally”. Let us assume that these respondents report on average 2 points lower than a bias-free sample (i.e., they report “never” instead of “hardly ever” and “occasionally”, “hardly ever” instead of “quite often”, and “occasionally” instead of “frequently”). Additionally, one-third of the respondents report on average 2 points higher than a bias-free sample (i.e., more toward “frequently”). The distribution of the overall sample, yielding an average correlation between the two variables of 0.55, is provided in Fig. 4. What this simulation shows is that method effects alone, in this case, response style (“nay-saying”, “yea-saying”), can cause strong correlations (see also De Winter and Dodou, 2017).

The problem illustrated here seems to be strikingly common in traffic psychology. One group of unnamed authors, for example, evaluated the acceptance of automated vehicles using the Unified Theory of Acceptance and Use of Technology (UTAUT). They

Figure 4 Distribution of Pearson product-moment correlation coefficients between two variables for a sample size of 300 when the correlation in the population is 0 (unbiased samples) and when the population correlation is 0 but response style contaminates the results (biased samples). The bins in this figure are 0.01 wide.

found positive correlations ($r = 0.5$ to 0.6 , all P -values < 0.001) between behavioral intentions to use an automated vehicle, on the one hand, and effort expectancy, social influence, facilitating conditions, and hedonic motivation, on the other. These findings, although correct from the viewpoint of null hypothesis significance testing, do not imply that one can predict real-life behavioral intentions that strongly. The positive correlations probably reflect a method effect or a form of social desirability or self-esteem which translates into response style.

The bottom line is that effect sizes should be reported and interpreted. Researchers should not focus solely on P -values: even trivially small effects can yield highly significant P -values, and strong effects are, of course, statistically significantly different from 0, but may not reflect the true state of the world. Possible remedies to common method biases are to measure predictor and criterion variables at different points in time, the use of forced-choice survey items (Bartram, 2007; Brown and Maydeu-Olivares, 2011; Nederhof, 1985), and the use of a criterion variable that is recorded rather than self-reported (Af Wählberg, 2017).

Letting the Statistical Test Depend on a Statistical Test

In traffic psychology, it often happens that researchers pretest their data. For example, a researcher may test for normality before deciding whether to conduct a parametric t -test or ANOVA or a nonparametric Wilcoxon rank-sum test, Kruskal–Wallis test, or Friedman test. A problem with pretesting is that the “numbers don’t remember where they came from” (Lord, 1953, p. 21), and that such tests may not have sufficient power for detecting violations of the assumptions of the follow-up tests (Rasch et al., 2011; Zimmerman, 2011).

Suppose a researcher is faced with two samples of data which he would like to statistically compare. The researcher decides to conduct a t -test or a Wilcoxon rank-sum test based on the result of a Shapiro–Wilk test of normality. The issue here is that, if the sample size is higher, the statistical power of the Shapiro–Wilk test will tend to be higher as well, and so the outcome of the Shapiro–Wilk test depends on sample size as well as the idiosyncratic nature of the dataset. It is much more efficient to decide beforehand which statistical test to use. For example, it is already well known that Driver Behaviour Questionnaire (DBQ) item data are heavily tailed (e.g., Mattsson, 2012). It may therefore be better to use tests which are robust to tailed distributions (e.g., Wilcoxon rank-sum tests, signed-rank tests, and Spearman’s rank-order correlations). No pretest is needed if prior research already reveals which type of test is most appropriate.

A computer simulation could prove the point. Suppose one wishes to test whether the central tendency of two distributions is different. The first distribution has a mean of 0 and a standard deviation of 1, and the second distribution has a mean of 1 and a standard deviation of 1 (i.e., Cohen’s $d = 1$). Furthermore, the sample size is 20 per group, and the first group features an outlier. More specifically, the value for the 20th participant in the first group equals 4 (i.e., the mean + 4 standard deviations).

Table 1 shows the results of a simulation study of a two-stage process, with 100,000 repetitions. That is, 100,000 times, 20 samples were drawn from the first distribution, and 20 samples were drawn from the second distribution, and the two samples were compared using an independent-samples t -test and a Wilcoxon rank-sum test, as well as a conditional test. In the conditional test, an independent-samples t -test was conducted when a Shapiro–Wilk test used on the first sample yielded $P \geq 0.05$, and a Wilcoxon rank-sum test was conducted when the same Shapiro–Wilk test yielded $P < 0.05$.

Table 1 reveals that the statistical power is higher for the Wilcoxon rank-sum test than for the t -test, which can be explained by the outlier. After all, it is well established that the t -test is not particularly robust to outliers. The conditional approach improves statistical power substantially compared to the independent-samples t -test but is still less powerful than the Wilcoxon rank-sum test.

Using an insurance policy analogy (Anscombe, 1960), it can be wise to choose a nonparametric test such as a Wilcoxon rank-sum test or a Welch’s t -test (Lakens, 2015a) and not use a pretesting approach. Such a test yields a slight loss of power compared to the regular t -test if the normality assumption is met. However, the insurance premium is only small for the high protection it offers against outliers or unequal variances.

More damaging outcomes can occur when the researcher chooses the statistical test based on statistical significance. For example, a researcher may decide to remove outliers and subsequently perform the statistical test again, or may first perform a regular t -test, and, if the result is not significant, perform a Wilcoxon-rank-sum test. Dropping or merging of experimental conditions, optional stopping, or adding covariates/moderator variables (e.g., age, gender) are similar examples. These types of so-called questionable research practices, which can dramatically increase false-positive rates, have been previously identified in psychological research (Bakker and Wicherts, 2014; Nelson et al., 2018), and may well be exacerbated in traffic psychology, an area that has been progressing in parallel to mainstream psychology and engineering.

Table 1 Results of a simulation study for detecting a significant difference between two groups in the presence of an outlier in one of the two groups

	Statistical power (% of 100,000 repetitions yielding $P < 0.05$)
Independent-samples t -test	56.7%
Wilcoxon rank-sum test	72.3%
Conditional test	66.9%

Note. The Shapiro–Wilk test yielded a significant effect in only 60.5% of the 100,000 repetitions.

Figure 5 *P*-value distribution (*P*-curve) in case there is no effect in the population. By “trying out” various statistical test and reporting the “best” effect, the false positive rate may increase substantially (from 5.0% to 14.1% in this simulation). The bins in this figure are 0.01 wide.

Fig. 5 illustrates the result of independent-samples *t*-tests in black. In this case, two samples with equal means and standard deviations were compared, $n = 20$ per group. The results of this simulation, performed with 100,000 repetitions, show that the distribution of the *P*-value is uniform (see also Lakens, 2015b).

The red line in Fig. 5 shows the results of statistical tests for the same data, but here we simulated researchers who engaged in questionable research practices. More specifically, the simulated researchers all performed an independent-samples *t*-test, a paired-samples *t*-test, an independent-samples *t*-test after automated outlier removal, and an independent samples *t*-test for subgroups. The latter could be done, for example, if the samples consist of 10 males and 10 females, and the researchers test for a difference in means for males and females separately. If the researchers use the minimum *P*-value among all five options, the *P*-values become lower than they should be. In this case, the false-positive rate has become 14.1%, that is, 14.1% of the 100,000 cases yielded $P < 0.05$.

In traffic psychology, a popular method is to perform a stepwise regression analysis. A stepwise analysis works by including statistically significant predictors only and removing variables when they are not significant, and suffers from similar problems as the problems as illustrated in Fig. 5. Further critique of stepwise regression analysis is provided by Antonakis and Dietz (2011) and Thompson (1989), amongst others.

In summary, the statistical test should not depend on another statistical test: Two-stage approaches can yield suboptimal statistical power and, more worryingly, peeking at the data and adjusting the statistical test accordingly increases the prevalence of false positives. Methods such as preregistration of one’s hypotheses (Nosek et al., 2018) can help prevent the issues mentioned in this section.

Violation of Independence

It often happens that the traffic psychologist computes correlation coefficients to explore relationships between variables collected in the experiment. For example, the researcher may be interested in the relationship between take-over time and the maximum absolute steering wheel angle. Fig. 6 shows a scatter plot of take-over time and maximum absolute steering wheel angle, as could have been obtained from a simulator-based experiment. In this case, the association between the two variables is moderate and not significantly different from 0 ($r = 0.27$, $P = 0.247$).

Typically, experiments contain multiple repetitions of the same scenario. For example, there may have been five identical take-over trials per time budget condition. In traffic psychology, the first author has seen it happening on numerous occasions that researchers inadvertently treat those repeated measures as independent. For the sake of argument, let us assume that participants are consistent with respect to themselves. This is a reasonable assumption in behavioral research, where in the long run, participants exhibit stable behavioral patterns (excluding learning, mood swings, etc.). Thus, it is assumed that the 20 participants output practically the same take-over time and the same maximum absolute steering wheel angle for each of the identical five take-over trials.

The corresponding scatter plot is drawn in Fig. 7; it contains the same data as in Fig. 6, except that there are now 100 data points because the repeated measures for the same persons are plotted separately, whereas the markers in Fig. 6 were assumed to reflect the

Figure 6 Example (simulated) data for an experiment on automation take-overs. The horizontal axis shows the take-over time (same data as the data in Fig. 1 for the 3 s time budget condition), and the vertical axis shows the maximum absolute steering wheel angle.

Figure 7 Example (simulated) data for an experiment on automation take-overs. The horizontal axis shows the take-over time, and the vertical axis shows the maximum absolute steering wheel angle. The data are the same as in Fig. 6, except that each value is now repeated five times. A small variation in take-over time was added (within the range of -0.1 s to 0.1 s) to assure that the markers are not overlapping.

Figure 8 Example (simulated) data for vehicle speed and the driver's vertical eye movements. These data were generated using a multi-sine approach and a random number generator.

average of the five trials. The correlation coefficient, as depicted in Fig. 7, is the same as before ($r = 0.27$), but the P -value is clearly lower ($P = 0.007$). The reason for the reduced P -value is that repeated samples are incorrectly treated as independent. In other words, the researcher has artificially multiplied the sample size by a factor 5.

Violation of independence can come in different guises. It occurs not only in the computation of P -values for correlation coefficients but also in other types of statistical tests (e.g., ANOVAs) and other data types, such as time series. Assume that a researcher computes the relationship between two signals. For example, the traffic psychologist may be interested in whether drivers are more likely to look at the road instead of the dashboard when the vehicle speed is higher. Accordingly, the researcher computes the correlation coefficient between vehicle speed in km/h and the vertical gaze angle in degrees, as measured with an eye-tracker in the car. In the example shown in Fig. 8, which involves simulated data, a correlation coefficient of 0.22 is observed. It often happens that the researcher claims that such a correlation is statistically significant from 0, by using all sampling instances as inputs. For example, the data shown in Fig. 8 have been recorded at 50 Hz, so 1 min of data involves 3000 samples, and the corresponding P -value is 8.37×10^{-34} . However, this P -value is clearly misleading and incorrect, as the adjacent sample points are correlated. In fact, the two signals shown in Fig. 8 were generated using a random number generator and are independent.

In summary, researchers in traffic psychology should ensure that the participants are the unit of analysis, not the repeated measurements of the same participants. It is also possible to treat multiple independent trials as the unit of analysis, an approach which tends to be taken in psychophysics (Smith and Little, 2018).

Conclusion

This article highlighted a number of common pitfalls in the use of statistics in traffic psychology. The take-home message of this work is that a single statistically significant P -value cannot be used to disprove one's null hypothesis, especially when the P -value is barely significant (e.g., $P = 0.04$) or when it is a surprising discovery. Furthermore, the article pointed out that effect sizes should always be considered and that decision-making should not be based on P -values only: sometimes even extremely small and practically insignificant effects are statistically significantly different from zero, or strong effects may exist which are not particularly interesting because "everything is correlated". We also showed that two-stage statistical procedures are inefficient and that data peeking increases the prevalence of false positives. Fourth, and finally, we highlighted the issue of violation of independence, which we believe is a common problem in the field.

The current article is far from complete, and there are a variety of other pitfalls that can be acknowledged. Other common mistakes are (1) the usage of the Kaiser criterion (e.g., counting the number of eigenvalues greater than 1 for deciding on the number of factors to retain in factor analysis), (2) confusing standardized and nonstandardized coefficients in a regression analysis, and (3) multicollinearity in the regression model (e.g., inputting strongly correlated variables, such as driver age and driver experience in years).

We hope that the present article can be of use to the applied researcher. Recognition of the presented pitfalls may improve the robustness of published findings in the area of traffic psychology.

Introduction and Illustrative Examples

Structural equation models (SEMs) include a broad range of data analysis techniques that are commonly used in social sciences to unravel complex patterns of (inter)relationships among different variables. Two main kinds of techniques can be seen as specific instances of a SEM:

- path analysis, that is in turn a generalization of multiple regression analysis, in which several different dependencies among different variables are jointly considered;
- confirmatory factor analysis, that can be applied to identify the underlying latent constructs of a larger set of manifest variables, that is, variables that can be directly measured through some experimental activity.

SEM in their most general form can therefore contain both (1) a structural model, that is describing the set of dependence relationships that the researcher is willing to study among the considered variables, and (2) a measurement model, aimed at capturing the relationships between a set of manifest variables, or indicators, with their corresponding latent variables, or unobserved constructs.

Fig. 1 shows an example of SEM in travel behavior research, where only a structural model is needed since all variables are manifest (Kroesen, 2017). No measurement model is then specified in this instance. The goal is to simultaneously model the levels of use of five different transport modes, in terms of total distance traveled in a day. Eight exogenous socioeconomic variables are considered, along with an additional set of three mediating variables that are affected by the characteristics of the subject on one hand, and that are in turn influencing the final outcome on the other. This multilevel model structure is one of the attracting features of SEM, since it allows for a more realistic representation of the reality, which seldom reflects a neat distinction between endogenous and exogenous variables. In this example, the total effects of a given socioeconomic characteristic on modal usages are in fact obtained by compounding the direct effects (8×5 relationships) plus the indirect effects through the mediating variables, thus offering a clearer insight of the phenomenon under consideration. Considering a different context, it has also to be noted that a multistage structure is an asset when dealing with panel data or dynamic models.

The conceptual model of **Fig. 1** shows that all possible structural relationships represented by arrows were estimated, but it is also possible to specify a more parsimonious model, where only a subset of these are considered. Within a SEM, it is also possible to estimate correlations among endogenous variables rather than structural relationships, or nonrecursive models where directions of causation are not unique and the existence of “causal loops” is tested, provided that the model itself is identified. Expanding the above example, a researcher might postulate that the levels of use of cars or public transport might in turn have an influence on the ownership of bikes and e-bikes.

A complementary example of SEM is provided in **Fig. 2**, this time considering a measurement model that was proposed to quantitatively define the concept of primary, or intrinsic utility of traveling (Diana, 2008). Following standard conventions, latent constructs are represented by ovals and manifest indicators by rectangles. No exogenous variables or dependence patterns among variables are considered here: arrows are linking the different latent variables with their respective indicators. Given the absence of structural relationships, this model can be seen as a confirmatory factor analysis that is empirically testing a theory, aimed at showing how the primary trip utility can be indirectly observed through a set of indicators. These latter are presented in the lower part of the figure and consist in a set of 20 items $y_1, \dots, y_{20}$ measured in a survey through semantic scales, therefore dealing with ordinal rather than metric variables.

Such manifest variables are not directly related to the primary utility construct, but they rather load on six different latent dimensions or aspects that can help in better understanding the phenomenon under consideration. In turn, the latter latent dimensions load on the second-order factor that is capturing the primary utility. Again, the possibility of defining multiple stages not only in structural but also in measurement models is one key feature of the method. The figure is showing with Greek letters the model parameters that were estimated, namely the first- and second-order factor loadings (respectively λ and γ), the variance of the first- and second-order measurement errors (respectively ϵ and ζ). Additionally, a measurement error

Figure 1 An example of SEM involving a path diagram. Source: Kroesen, 2017.

covariance between two manifest items was also estimated, but of course additional ones could have been included as well based on theory guidance.

As already mentioned, more general instances than the two above examples are commonly studied, where some of the variables in the structural model (either endogenous or exogenous) are latent and both structural and measurement models are therefore jointly estimated.

The SEM concept has been developed from the 1970s and it is nowadays one of the most widely used methods in social sciences. The present contribution will not deal with technical issues such as SEM statistical assumptions, model specification, estimation, fit assessment and validation, since they are widely and thoroughly covered by existing manuals, at different levels of technical discussion and for all kinds of readership. The “Further readings” section presents an essential selection of these sources, including texts with different technical levels. Besides, many different SEM softwares have been developed in recent years and they generally reached a maturity stage that allow the analyst to enjoy a wide range of functionalities in a relatively user-friendly environment. Examples include programs such as *EQS*, *LISREL*, and *Mplus*, but also dedicated applications or modules of statistical analysis softwares such as *CALIS* for the SAS environment, *Amos* for SPSS, *SEPATH* for STATISTICA and the *lavaan* and *sem* packages for the open source software R.

In the following, the intention is rather to offer some guidance on when developing a SEM might be good option in the transport research domain, in view of the current state of the art and available alternatives. The related discussion is developed in the following subhead. To better illustrate this point, some examples of recent SEM applications dealing with different topics within the travel behavior research sector will then be presented. The chapter will then end with some speculation on the potential of this method to serve the transportation research community in the (near) future.

SEM Ambits of Use

The two previous examples have shown how the flexibility of SEM can be exploited in a wide range of situations. Yet such flexibility is also inherently bringing some limitations in its best ambits of use. In particular, SEM has no underpinning theory, unlike e.g. discrete

Figure 2 An example of confirmatory factor analysis through SEM. Source: [Diana, 2008](#).

choice models, which are based on the consumer theory. The researcher is left with the responsibility of adopting or developing a sufficiently robust theoretical background before specifying a SEM, thus making SEM a confirmatory rather than an exploratory research technique. Conversely, the lack of such framework should not lead to considering the flexibility of the tool simply as a convenient way to build a model that fits at best the available dataset. This is perhaps the single most common misuse of SEM that is encountered in the literature.

Traditionally, SEM has been seen as a technique that can only handle continuous endogenous variables. However, estimation methods are also available whenever the model outcomes are rather ordinal or binary, albeit quite larger sample size are required in such cases. On the other hand, SEM cannot deal with dependent variables having more than two categories, that can be rather analyzed through multivariate logistic regression or its counterpart in the econometric domain, the multivariate logit model. Concerning the latter, the relatively recent rise of the Integrated Choice and Latent Variables (ICLV) models that can jointly estimate structural relationships and factor loadings of latent variables gives the analyst a valuable alternative to SEM whenever (1) the outcome variable is categorical and (2) the theoretical background of the consumer theory is appropriate for the problem under consideration.

In common with other techniques making use of latent variables, SEM has been criticized for being a descriptive method that is of little use for forecasting purposes. Indeed, SEM can give additional insights that can be later used to better specify forecasting models, while avoiding or at least properly considering common specification errors or related issues such as multicollinearity, ecological fallacy or the confusion between correlation and causation, just to name a few.

SEM Use in Travel Behavior Research

SEM started being consistently used by the transport research community only at the end of the 20th century. The interested reader is referred to [Golob \(2003\)](#) for a review of these early applications and a discussion on the most promising fields where the technique can be applied, which is largely still valid nowadays. In the following, we will build on that work to identify some more recent lines of research in the transportation sector that have been developed by employing SEM techniques, without any claim of being exhaustive given the nature of the present contribution.

Due to the possibility of modeling complex relationships across different variables, one of the earlier SEM applications was related to activity-based models. Many studies resort on the method to clarify the dynamics of time allocation among various activities and the related travel durations and modal choices, considering a range of personal characteristics and inter-personal interactions ([Cheng et al., 2019](#); [Fyhri and Hjorthol, 2009](#); [Sharmeen et al., 2014](#); [Scheiner, 2020](#); [Susilo and Liu, 2016](#); [Wang and Law, 2007](#)). A related field is the study of the intertwined relationship between built environment and travel choices, where SEM can

help in sorting out self selection and simultaneity biases (Mokhtarian and Cao, 2008; Wang and Lin, 2019), along with the mediating role of additional variables such as car ownership (Van Acker and Witlox, 2010).

The link between psychological constructs (such as attitudes, perceptions, satisfaction, and wellbeing) and travel-related intentions and behaviors is another typical field where SEM has been successfully employed (Bamberg et al., 2007; De Oña et al., 2016; Ingvardson and Nielsen, 2019; Lai and Chen, 2011; Lois and López-Sáez, 2009; Kaplan et al., 2019; Kroesen, 2014; Scheiner and Holz-Rau, 2007). SEM seems particularly promising when the focus is on innovative transport services and specific social groups, where choice alternatives might not be well known and different behavioral theories might be appropriate (Bennett et al., 2019; Kroesen, 2017; Mohamed et al., 2016; Neoh et al., 2018; Wang et al., 2019; Will and Schuller, 2016).

Travel safety research can be seen under a similar viewpoint, whenever the goal is to relate risk and safety perceptions or personality traits with behaviors and distraction, mainly in relation with car- and two-wheeled vehicles usage or walking. Indeed, this research domain has possibly witnessed the largest proportion of SEM studies in more recent years (e.g., Chataway et al., 2014; Chen and Donmez, 2016; Dinh et al., 2020; Jovanović et al., 2011; Kummeneje and Rundmo, 2019; Mallia et al., 2015; Susilo et al., 2015; Tazul Islam et al., 2017; Useche et al., 2018; Wong et al., 2018; Zhao et al., 2019). Additional applications include the effects of road and driver characteristics, environmental factors and urban forms on traffic safety (Kamel and Sayed 2019; Lee et al., 2008; Najaf et al., 2018).

Nowadays, travel demand management strategies (such as travel behavior change programs or travel nudging) are often implemented along with more concrete interventions on the transport system offer to maximize the effectiveness of the interventions. Studying how such a mixture of hard and soft (or push and pull) measures interact usually requires putting forward a behavioral theory, often developed by environmental psychologists, that can be empirically tested through SEM (Bamberg et al., 2011).

Future SEM Prospects

The above reviewed state of the art of SEM in the transport sector can give us some hints on how such methods can contribute in tackling future research endeavors in this area.

To date, the common mindset of transport modelers and practitioners is understandably to explain observed mobility behaviors on the basis of different factors, including sociodemographics, psychological constructs and characteristics of the transport system. In turn, decision-making processes are often based on an economic evaluation of different alternatives, such as in cost-benefit analysis, that is largely eased by a consistent theoretical framework that is directly giving key inputs such as value of travel times or elasticity values. Yet travel choices might not be purely endogenous, since they can in turn influence other elements in the life of individuals. Failing to acknowledge such loops might lead to a poor understanding of mobility phenomena and undermine the effectiveness of advice given to policy makers to tackle the complex problems that affect contemporary transport systems.

The above caveat seems particularly critical when dealing with specific issues that are, however, gaining importance in the study of transport systems. One good example is the impact of disruptive technologies, such as the role of ubiquitous travel information in shaping mobility behaviors, driver reactions to improved safety devices or the potential diffusion of the connected, autonomous, shared and electric (CASE) paradigm in road transport (Diana, 2010). Related technology applications call for a behavioral reaction from the traveler side, who might range from an aprioristic refusal to an enthusiastic adoption. Such reactions go much beyond a rational decision-making context, with the added complexity of a high degree of dynamism of the whole process (early adopters versus latecomers) that can negatively affect the reliability of model-based forecasts, especially if based on cross-sectional experiments. In such situations, taking not for granted the usual attitude – behavior direction of causation with the mediating role of the utility construct could lead to better insights.

Moving from research topics to research methods, SEM can be seen as a tool that may work well together with some agnostic, or perhaps even uninformed, research approaches, such as the analysis of big data, that are breaking through the “comfort zone” made of well-established practices and consolidated paradigms of the transportation research community and that are capturing a lot of attention of both decision makers and the general public. Those alternative approaches are often carried out by scholars, such as physicists and computer scientists, that simply “let the data speak”, by applying data mining methods and algorithms that they master in the transportation research field, like they are used to do in any other domain. There is indeed a good potential to strengthen the connections between the “big data” and “small data” research communities dealing with transport issues (Chen et al., 2016), and SEM could be a flexible enough tool to help achieving this objective. Data can indeed speak, but SEM can be very useful in actually understanding what data are telling us.
